Over the last 30 years, Carol M. Porth’s text, *Pathophysiology: Concepts of Altered Health States*, has become widely known as a seminal text in pathophysiology for nursing and health profession students. It is a testament to her extensive knowledge, skills, and commitment that she succeeded in creating such a student-friendly and, at the same time, state-of-the-art book. It is a great honor to carry forward this tradition as the new author of the ninth edition of *Porth’s Pathophysiology*.

The goal for this edition has been to retain the text’s solid foundation while updating and incorporating new advances in science and technology. Once again, talented clinicians, researchers, and scholars have contributed their expertise and knowledge to the book. The major emphasis continues to be on relating normal body functioning to the physiologic changes that occur as a result of disease, as well as on the body’s ability to compensate for these changes through mechanisms of healing and those that work to prevent and resist disease. Although primarily designed as a textbook, the book also serves as a reference that students will find useful throughout their educational program and, eventually, in practice.

This edition marks the 30th anniversary of *Pathophysiology: Concepts of Altered Health States*. From its first edition published in 1982, it has grown to become a trusted and definitive resource for students, instructors, and health care professionals.

The goal for each edition has been to develop a text that is current, accurate, and presented in a logical manner. While its vision and objectives have remained the same throughout the editions, the methods used to gather, analyze, present, and deliver the information have changed. Myriad cultural, political, and technological factors have helped to shape the text, and it is now a reflection of the global community. Technology has allowed me to work with contributors from around the world, to harvest information from a seemingly unlimited reservoir, and to deliver the information to an ever-growing audience.

With each edition, the task at hand was to create a learning environment that would, in the words of Chinese scholars, “open the gates of knowledge” to the reader. The art of opening up a subject and generating enthusiasm for that subject is what produces autonomy and ultimately, an independent learner. While other physiology-based texts take a “how-to” or heavily application-oriented approach, that was not the intent here. Rather, this text focuses on the scientific basis upon which the practice components of the health professions are based, fostering a practitioner with the knowledge and skills to develop creative solutions within a dynamic profession.

A holistic conceptual framework uses body systems as an organizing framework and demonstrates how the systems are interrelated. Selection of content was based on common health problems across the lifespan, and recent advances in the fields of genetics, immunology, microbiology, and molecular biology are included. Concepts are presented in a manner that is logical and understandable for students, building from basic to more complex. The chapters are arranged so that common accompaniments to disease states, such as inflammation and repair, genetic control of cell function and inheritance, and immunologic processes, appear in the early chapters before the specific discussions of particular disease states.

Proven strengths of the text include the expanded chapters on health and disease; nutrition; sleep and sleep disorders; pediatrics; gerontology; and thought, emotion, and mood disorders. Advances in health care are presented through the inclusion of international studies, WHO guidelines, and the health variants of diverse populations. I am pleased to present this new edition and to play a role in continuing the legacy of this valuable resource for students, instructors, and health professionals.

Sheila C. Grossman
them to memorize miscellaneous facts. The Understanding features that appear in some chapters break physiologic processes and phenomena into their sequential parts, providing insight into the many opportunities for disease to disrupt the processes. Review exercises are included to provide practice in using the conceptual approach in solving problems related to patient scenarios. Other helpful tools include a glossary and a table of normal laboratory values.

In developing content for the previous editions, my perspective as a nurse–physiologist led to an approach based on relating normal body functioning to the physiologic changes that participate in disease production and that occur as a result of disease. I also focused on the body’s remarkable ability to compensate for these changes. The beauty of physiology is that it integrates all of the aspects of human genetics, molecular and cellular biology, and anatomy and physiology into a functional whole that can be used to explain both the physical and psychological aspects of altered health. In its very essence, each edition has reflected my desire to share the beauty of the human body and to emphasize that in disease as in health, there is more “going right” in the body than is “going wrong.”

Throughout its 30 years, authoring the book has been a meaningful endeavor. The preparation of each edition has been a challenging and humbling task. I have experienced great joy and satisfaction in engaging the reader and sharing the excitement and wonder that I have for the physiologic basis of life and altered health. With this ninth edition, we welcome a new voice and vision to the enterprise as Dr. Sheila Grossman leads the publishing effort for this new edition and shares in the experience of “opening the gates of knowledge.”

Carol Mattson Porth
This book was written with the intent of making the subject of pathophysiology an exciting exploration that relates normal body functioning to the physiologic changes that occur as a result of disease, as well as the body's remarkable ability to compensate for these changes. Indeed, it is these changes that represent the signs and symptoms of disease.

Using a book such as this can be simplified by taking time out to find what is in the book and how to locate information when it is needed. The table of contents at the beginning of the book provides an overall view of the organization and content of the book. It also provides clues as to the relationships among areas of content. For example, the location of the chapter on neoplasia within the unit on cell function and growth indicates that neoplasms are products of altered cell growth. The index, which appears at the end of the book, can be viewed as a road map for locating content. It can be used to quickly locate related content in different chapters of the book or to answer questions that come up in other courses.

ORGANIZATION

The book is organized into units and chapters. The units identify broad areas of content, such as alterations in the circulatory system. Many of the units have an introductory chapter that contains essential information about the structure and function of the body systems that are being discussed in the unit. These chapters provide the foundation for understanding the pathophysiology content presented in the subsequent chapters. The chapters focus on specific areas of content, such as heart failure and circulatory shock. The chapter outline that appears at the beginning of each chapter provides an overall view of the chapter content and organization.

READING AND LEARNING AIDS

In an ever-expanding world of information, you will not be able to read, let alone remember, everything that is in this book, or in any book, for that matter. With this in mind, we have developed a number of special features that will help you focus on and master the essential content for your current as well as future needs.

The objectives that appear at the beginning of each major area of content provide a focus for your study. After you have finished each of these areas of content, you may want to go back and make sure that you have met each of the objectives.

After completing this section of the chapter, you should be able to meet the following objectives:

- State a definition for young-old, middle-old, and old-old and characterize the changing trend in the older adult population.
- Discuss theories of biologic aging.

It is essential for any professional to use and understand the vocabulary of his or her profession. Throughout the text, you will encounter terms in italics. This is a signal that a word and the ideas associated with it are important to learn. In addition, a glossary is provided to help you expand your vocabulary and improve your comprehension of what you are reading. The glossary contains concise definitions of frequently encountered terms. If you are unsure of the meaning of a term you encounter in your reading, check the glossary in the back of the book before proceeding.

BOXES

Boxes are used throughout the text to summarize and highlight key information. You will frequently encounter two types of boxes: Key Points boxes and Summary boxes.

One of the ways to approach learning is to focus on the major ideas or concepts rather than trying to memorize a list of related and unrelated bits of information. As you have probably already discovered, it is impossible to memorize everything that is in a particular section or chapter of the book. Not only does your brain have a difficult time trying to figure out where to store all the different bits of information, your brain does not know how to retrieve the information when you need it. Most important of all, memorized lists of content can seldom, if ever, be applied directly to an actual clinical situation. The Key Points boxes guide you in identifying the major ideas or concepts that form the foundation for truly understanding the major areas of content. When you understand the concepts in the Key Points boxes, you will have a framework for remembering and using the facts given in the text.

KEY POINTS

BRAIN INJURY AND LEVELS OF CONSCIOUSNESS

- Consciousness is a global function that depends on a diffuse neural network that includes both cerebral hemispheres and activity of the RAS.
- Impaired consciousness implies diffuse brain injury to both cerebral hemispheres simultaneously or the RAS at any level (medulla through thalamus).
- In contrast, local brain injury causes focal neurologic deficit but does not disrupt consciousness.

The Summary boxes at the end of each section provide a review and a reinforcement of the main content that has been covered. Use the summaries to assure that you have covered and understood what you have read.
To the Reader

ILLUSTRATIONS AND PHOTOS

The full-color illustrations will help you to build your own mental image of the content that is being presented. Each drawing has been developed to fully support and build upon the ideas in the text. Some illustrations are used to help you picture the complex interactions of the multiple phenomena that are involved in the development of a particular disease; others can help you to visualize normal function or understand the mechanisms whereby the disease processes exert their effects. In addition, photographs of pathologic processes and lesions provide a realistic view of selected pathologic processes and lesions.

TABLES AND CHARTS

Tables and charts are designed to present complex information in a format that makes it more meaningful and easier to remember. Tables have two or more columns, and are often used for the purpose of comparing or contrasting information. Charts have one column and are used to summarize information.

**TABLE 31.1: CLASSIFICATION OF BLOOD PRESSURE FOR ADULTS AND RECOMMENDATIONS FOR FOLLOW-UP**

<table>
<thead>
<tr>
<th>BLOOD PRESSURE CLASSIFICATION</th>
<th>SYSTOLIC BP (mm Hg)</th>
<th>DIASTOLIC BP (mm Hg)</th>
<th>FOLLOW-UP RECOMMENDATIONS FOR INITIAL TREATMENT</th>
</tr>
</thead>
<tbody>
<tr>
<td>Normal</td>
<td>&lt; 120</td>
<td>&lt; 80</td>
<td>Redo checking in 3 months</td>
</tr>
<tr>
<td>Prehypertensive</td>
<td>120–139</td>
<td>&gt; 80–89</td>
<td>Redo checking in 2 years</td>
</tr>
<tr>
<td>Stage 1 hypertension</td>
<td>140–159</td>
<td>&gt; 90–99</td>
<td>Continuously monitor blood pressure, reduce risk factors, and follow-up as above.</td>
</tr>
<tr>
<td>Stage 2 hypertension</td>
<td>≥ 160</td>
<td>&gt; 100</td>
<td>Refer to a specialist who can help you better control your blood pressure.</td>
</tr>
</tbody>
</table>

*Note: Blood pressure measurements were taken after at least 5 minutes of rest. Values reflect the average of two or more readings taken at different times.*

**FIGURE 35.8** Lobule of the lung, showing the bronchial smooth muscle fibers, pulmonary blood vessels, and lymphatics.

UNDERSTANDING PHYSIOLOGIC PROCESSES

Understanding boxes focus on the physiologic processes and phenomena that form the basis for understanding disorders presented in the text. This feature breaks a process or phenomenon down into its component parts and presents it in a sequential manner, providing an insight into the many opportunities for disease processes to disrupt the sequence.

**CHART 31.1: TARGET ORGAN DAMAGE**

- Heart
  - Left ventricular hypertrophy
  - Angina or prior myocardial infarction
  - Prior coronary revascularization
  - Heart failure
- Brain
  - Stroke or transient ischemic attack
  - Chronic kidney disease
  - Peripheral vascular disease
  - Retinopathy

MATERIAL FOR REVIEW

An important feature has been built into the text to help you verify your understanding of the material presented. After you have finished reading and studying the chapter, work on answering the review exercises at the end of the chapter. They are designed to help you integrate and synthesize material. If you are unable to answer a question, reread the relevant section in the chapter.

REVIEW EXERCISES

1. A newborn girl was found to have DDH during a routine screening examination.
   A. Describe the anatomic abnormalities that are present in the disorder.
   B. Explain the need for early treatment of DDH.

2. A 12-year-old girl was noted to have asymmetry of the shoulders, scapular height, and pelvic height during routine physical examination. On x-ray examination, she is found to have a 30-degree curvature of the spine.
   A. What possible treatments are available for this girl?
   B. Describe the physical problems associated with progressive scoliosis.

3. A 60-year-old postmenopausal woman presents with a compression fracture of the vertebral body. She has also noticed increased backache and loss of height over the past few years.
   A. Explain how the lack of estrogen and aging contribute to the development of osteoporosis.
   B. What other factors should be considered when assessing the risk for development of osteoporosis?
   C. What is one way to measure bone density?
   D. Name the two most important factors in preventing osteoporosis.
   E. What medications might be used to treat this woman’s condition?

APPENDIX

The appendix, Lab Values, provides rapid access to normal values for many laboratory tests, as well as a description of the prefixes, symbols, and factors (e.g., micro, μ, 10⁻⁶) used for describing these values. Knowledge of normal values can help you to put abnormal values in context.

We hope that this guide has given you a clear picture of how to use this book. Good luck and enjoy the journey!
INSTRUCTOR RESOURCES

This ninth edition comes with a collection of ancillary materials designed to help you plan learning activities and evaluate students’ learning. The Instructor Resources are available online at thePoint—http://thepoint.lww.com—and include information and activities that will help you engage your students throughout the semester, including the following:

- Guided Lecture Notes that walk you through the chapter learning objective by learning objective with integrated references to the PowerPoint presentations
- Image Bank
- Test Generator
- Prelecture Quizzes
- Discussion Topics
- Assignments
- Case Studies with critical-thinking/discussion questions
- Online eBook
- Journal Articles

STUDENT RESOURCES

Students can also visit thePoint to access the following learning tools:

- Animations of selected pathophysiologic processes
- Links to relevant journal articles
- Student Review Questions for every chapter

STUDY GUIDE

Study Guide for Porth’s Pathophysiology: Concepts of Altered Health States reinforces and complements the text by helping you assess and apply your knowledge through case studies and a variety of question styles, including multiple choice, fill-in-the-blank, matching, short answer, and figure-labeling exercises that will help you practice for the NCLEX.

Practice makes perfect. And this is the perfect practice

PrepU is an adaptive learning system designed to improve students’ competency mastery and provide instructors with real-time analysis of their students’ knowledge at both a class and individual student level.

PrepU demonstrates formative assessment—it determines what students know as they are learning, and focuses them on what they are struggling with, so they do not spend time on what they already know. Feedback is immediate and remediates students back to this specific text, so they know where to go back to the text, read, and help understand a concept.

Adaptive and personalized

No student has the same experience—PrepU recognizes when a student has reached “mastery” of a concept before moving them on to higher levels of learning. This will be a different experience for each student based on the number of questions they answer and whether they answer them correctly. Each question is also “normed” by all students in PrepU around the country—how every student answers a specific question generates the difficulty level of each question in the system. This adaptive experience allows students to practice at their own pace and to study much more effectively.

Personalized reports

Students get individual feedback about their performance, and instructors can track class statistics to gauge the level of understanding. Both get a window into performance to help identify areas for remediation. Instructors can access the average mastery level of the class, students’ strengths and weaknesses, and how often students use PrepU. Students can see their own progress charges and strengths and weaknesses—so they can continue quizzing in areas where they are weaker.

Mobile optimized

Students can study anytime, anywhere with PrepU, as it is mobile optimized. More convenience equals more quizzing and more practice for students!

There is a PrepU resource available with this book! For more information, visit http://thepoint.lww.com/PrepU
With the first edition of *Pathophysiology: Concepts of Altered Health States*, an exciting and challenging journey began. My companions on this journey were many. Each of the many persons who participated in the creation of this long-standing work made a unique contribution.

The contributing authors are deserving of special recognition as the ninth edition bears the indelible imprint of their skill and expertise. Many of them have been with the book since its early editions, and the text and figures they created endure as much of what they authored appears in this revision. Given my sincere appreciation for their work, I would be remiss in not recognizing and acknowledging their authorship. Those I would like to acknowledge and thank include the following:

- Judith Aberg, MD, Associate Professor, New York University School of Medicine, Principal Investigator, AIDS Clinical Trial Unit and Director HIV, Bellevue Hospital Center. Chapter 16, Acquired Immunodeficiency Syndrome.
- Toni Ballestrieri, RN, BSN, CCNS, Milwaukee, Wisconsin. Chapter 32, Disorders of Cardiac Function.
- Anna Barkman, RN, MSN, CCNS, Faculty School of Nursing, Mount Royal College, Calgary, Alberta, Canada. Chapter 34, Heart Failure and Circulatory Shock.
- Diane Book, MD, Assistant Professor, Department of Neurology, Medical College of Wisconsin. Chapter 20, Disorders of Brain Function.
- Edward W. Carroll, PhD (Deceased), Clinical Assistant Professor, Department of Biomedical Sciences, Marquette University. Chapter 4, Cell and Tissue Characteristics; Chapter 6, Genetic Control of Cell Function and Inheritance; Chapter 17, Organization and Control of Neural Function; Chapter 23, Disorders of Visual Function.
- Robin Curtis, PhD, Retired Professor, Department of Cellular Biology, Neurobiology and Anatomy, Medical College of Wisconsin. Chapter 17, Organization and Control of Neural Function; Chapter 23, Disorders of Visual Function.
- W. Michael Dunn Jr, PhD, Professor of Pathology and Immunology, Washington University School of Medicine. Chapter 12, Mechanisms of Infectious Disease.
- Jason Faulhaber, MD, Fellow, Division of Infectious Diseases and Immunology, New York University School of Medicine. Chapter 16, Acquired Immunodeficiency Syndrome.
- Suzanne Fontana, RN, PhD, APRN-BC, Associate Professor and Family Nurse Practitioner, College of Nursing, University of Wisconsin – Milwaukee. Chapter 24, Disorders of Hearing and Vestibular Function.
- Kathryn Gaspard, PhD, Clinical Associate Professor Emerita, College of Nursing, University of Wisconsin – Milwaukee. Chapter 25, Blood Cells and the Hematopoietic System; Chapter 26, Disorders of Hemostasis; Chapter 27, Disorders of Red Blood Cells.
- Safak Guven, MD, MBA, FACE, FACP, Las Vegas, Nevada. Chapter 50, Diabetes Mellitus and the Metabolic Syndrome, with Glenn Matfin and Julie Kuenzi.
- Surena Hung, MD, Assistant Professor, Department of Neurology, Medical College of Wisconsin. Chapter 19, Disorders of Motor Function.
- Scott A. Jens, OD, FAAO, Director Optometry, Isthmus Eye Care, Middleton, Wisconsin. Chapter 23, Disorders of Visual Function.
- Mary Kay Jiricka, RN, MSN, CCRN, APN-BC, Cardiac Intensive Care Unit, Aurora St. Luke’s Medical Center, Milwaukee, Wisconsin. Chapter 11, Activity Tolerance and Fatigue.
- Mary Pat Kunert, RN, PhD (Deceased), Associate Professor, College of Nursing, University of Wisconsin – Milwaukee. Chapter 9, Stress and Adaptation; Chapter 10, Alterations in Temperature Regulation.
- Nathan A. Ledeboer, PhD, Assistant Professor of Pathology, Medical College of Wisconsin. Chapter 12, Mechanisms of Infectious Disease.
- Kim Litwack, RN, PhD, FAAN, APNP, Chapter 18, Somatosensory Function, Pain, and Headache; Chapter 35, Structure and Function of the Respiratory System; Chapter 40, Disorders of Acid–Base Balance.
- Judy Wright Lott, RN, PhD, DSN, FAAN, Dean and Professor of Nursing, Louise Herrington School of Nursing, Baylor University, Waco, Texas. Chapter 2, Concepts of Altered Health in Children.
- Patricia McCowen Mehring, RN, MSN, WHNP, Nurse Practitioner of OB-GYN, Medical College of Wisconsin. Chapter 53, Structure and Function of the Female Reproductive System; Chapter 54, Disorders of the Female Reproductive System; Chapter 55, Sexually Transmitted Infections.
- Carrie J. Merkle, RN, PhD, FAAN, Associate Professor, College of Nursing, University of Arizona, Tucson, Arizona. Chapter 5, Cellular Adaptation, Injury, and Death; Chapter 8, Neoplasia.
- Kathleen Mussato, RN, PhD, Research Manager, Henna Heart Center, Children’s Hospital of Wisconsin. Chapter 32, Disorders of Cardiac Function (Heart Disorders in Children).
- Janice Kuiper Pikna, RN, MSN, CS, Clinical Nurse Specialist—Gerontology Froedtert Hospital, Milwaukee, Wisconsin. Chapter 3, Concepts of Altered Health in Older Adults.
Acknowledgments

• Sandra Kawczynski Pasch, RN, MS, MA, Assistant Professor, Columbia College of Nursing, Milwaukee, Wisconsin. Chapter 22, Disorders of Thought, Mood, and Memory.
• Joan Pleus, RD, MS, CDE, Program Manager/Biomedical Core, Clinical Research Center, Medical College of Wisconsin. Chapter 47, Alterations in Nutritional Status.
• Charlotte Pooler, RN, BScN, MN, PhD (Nursing), CNCC (C), CNC (C), Director, Baccalaureate Nursing Program, Grant MacEwan College, Edmonton, Alberta, Canada. Chapter 37, Disorders of Ventilation and Gas Exchange.
• Debra Bancroft Rizzo, RN, MSN, FNP-C, Nurse Practitioner, Rheumatic Disease Center, Glendale, Wisconsin. Chapter 59, Disorders of Musculoskeletal Function: Rheumatic Disorders.
• Gladys Simandl, RN, PhD, Professor Columbia College of Nursing, Glendale, Wisconsin. Chapter 60, Structure and Function of the Skin; Chapter 61, Disorders of Skin Integrity and Function.
• Cynthia Sommer, PhD, MT (ASCP), Associate Professor Emerita, Department of Biological Sciences, University of Wisconsin. Chapter 13, Innate and Adaptive Immunity; Chapter 14, Inflammation, Tissue Repair, and Wound Healing.
• Jill Winters, RN, PhD, Associate Professor and Director of Research and Scholarship, Marquette University, Milwaukee, Wisconsin. Chapter 33, Disorders of Cardiac Conduction and Rhythm.

And for the chapters we contributed as author and coauthor

Carol M. Porth, RN, MSN, PhD (physiology), FAHA. Chapter 1, Concepts of Health and Disease; Chapter 7, Genetic and Congenital Disorders; Chapter 15, Disorders of the Immune Response; Chapter 21, Sleep and Sleep Disorders; Chapter 28, Disorders of White Blood Cells and Lymphoid Tissues; Chapter 29, Structure and Function of the Cardiovascular System; Chapter 31, Disorders of Blood Pressure Regulation; Chapter 36, Respiratory Tract Infections, Neoplasms, and Childhood Disorders; Chapter 38, Structure and Function of the Kidney; Chapter 40, Disorders of Acid–Base Balance, with Kim Litwack; Chapter 41, Disorders of Renal Function; Chapter 42, Acute Renal Failure and Chronic Kidney Disease; Chapter 43, Disorders of the Bladder and Lower Urinary Tract; Chapter 44, Structure and Function of the Gastrointestinal System; Chapter 45, Disorders of Gastrointestinal Function; Chapter 46, Disorders of Hepatobiliary and Exocrine Pancreas Function; Chapter 56, Structure and Function of the Musculoskeletal System.

Glenn Matfin, BSc (Hons), MB, ChB, DCM, FPPM, FACE, FACP, FRCP. Chapter 30, Disorders of Blood Flow in the Systemic Circulation; Chapter 39, Disorders of Fluid and Electrolyte Balance; Chapter 48, Mechanisms of Endocrine Control; Chapter 49, Disorders of Endocrine Control of Growth and Metabolism; Chapter 50, Diabetes Mellitus and the Metabolic Syndrome; Chapter 51, Structure and Function of the Male Genitourinary System; Chapter 52, Disorders of the Male Genitourinary System.

Other people who deserve recognition

Dr. Kathryn Gaspard also deserves recognition. Dr. Gaspard has been with the book since its early editions, providing consultation and insight into the development of the book’s content and illustrations. Georgianne Heymann, who has also been with the book since its early editions, assisted in editing the manuscript and provided encouragement and support when the tasks associated with manuscript preparation became most frustrating.

It is often said that a picture is worth a thousand words. This is particularly true in a book such as this, where illustrations form the basis for understanding difficult concepts. Illustrations in this book owe their origin to Carole Hilmer, who developed illustrations for the first five editions of the book, as well as Jennifer Smith, Anne Rains, and Wendy Jackelow, who continued the work of developing many new illustrations and modifying the old illustrations.

To those at Lippincott Williams & Wilkins (formerly J.B. Lippincott), who first offered me this opportunity, I thank you for your support and confidence in me through the publishing process. The editorial and production staff along with reviewers and consultants offered advice and guidance that were invaluable in preparing the work.

Without the students in the classes I have taught over the years, there would be no book. They deserve a special salute, for they are the inspiration upon which this book was founded. Within the ever-changing field of health care, it was through my students’ eyes that I was able to see their “real world” of patient care. They provided the questions, suggestions, and contact that directed the organization and selection of content for the book.

And last, but certainly not least, I would like to acknowledge my family and my friends for what seemed to be unlimited patience, understanding, and encouragement throughout the journey.

I have been very fortunate in this collective experience to have been surrounded by people that I would deem kindred spirits. Thank you all.

   THE IMMUNE RESPONSE 276
   Cytokines and Their Role in Immunity 277
   INNATE IMMUNITY 282
   Epithelial Barriers 282
   Cells of Innate Immunity 283
   Pathogen Recognition 284
   Soluble Mediators of Innate Immunity 286
   The Complement System 287
   ADAPTIVE IMMUNITY 288
   Antigens 288
   Cells of Adaptive Immunity 291
   B Lymphocytes and Humoral Immunity 294
   T Lymphocytes and Cellular Immunity 297
   Lymphoid Organs 300
   Active versus Passive Immunity 302
   Regulation of the Adaptive Immune Response 302
   DEVELOPMENTAL ASPECTS OF THE IMMUNE SYSTEM 303
   Transfer of Immunity from Mother to Infant 303
   Immune Response in the Older Adult 304
## 14 Inflammation, Tissue Repair, and Wound Healing 306

**THE INFLAMMATORY RESPONSE** 306  
Acute Inflammation 307  
Chronic Inflammation 317  
Systemic Manifestations of Inflammation 317  
**TISSUE REPAIR AND WOUND HEALING** 319  
Tissue Repair 319  
Wound Healing 322

## 15 Disorders of the Immune Response 329

**IMMUNODEFICIENCY DISORDERS** 329  
Humoral (B Cell) Immunodeficiencies 332  
Cell-Mediated (T Cell) Immunodeficiencies 334  
Combined T-Cell and B-Cell Immunodeficiencies 336  
Disorders of the Complement System 337  
Disorders of Phagocytosis 338  
Stem Cell Transplantation 340  
**HYPERSENSITIVITY DISORDERS** 341  
Type I, Immediate Hypersensitivity Disorders 341  
Type II, Antibody-Mediated Disorders 345  
Type III, Immune Complex-Mediated Disorders 346  
Type IV, Cell-Mediated Hypersensitivity Disorders 347  
Latex Allergy 349  
**TRANSPLANTATION** 350  
Mechanisms Involved in Transplant Rejection 351  
**AUTOIMMUNE DISEASE** 353  
Immunologic Tolerance 353  
Mechanisms of Autoimmune Disease 355  
Diagnosis and Treatment of Autoimmune Disease 356

## 16 Acquired Immunodeficiency Syndrome 361

**THE AIDS EPIDEMIC AND TRANSMISSION OF HIV INFECTION** 361  
Emergence of AIDS 362  
Transmission of HIV Infection 362  
**PATHOPHYSIOLOGY AND CLINICAL COURSE** 363  
Molecular and Biologic Features of HIV 363  
Classification and Phases of HIV Infection 366  
Clinical Course 367  
**PREVENTION, DIAGNOSIS, AND TREATMENT** 373  
Prevention 374  
Diagnostic Methods 374  
Treatment 375  
HIV INFECTION IN PREGNANCY AND IN INFANTS AND CHILDREN 377  
Preventing Perinatal HIV Transmission 377  
Diagnosis of HIV Infection in Children 377  
Clinical Presentation of HIV Infection in Children 377

## UNIT V DISORDERS OF NEURAL FUNCTION 381

**NERVOUS TISSUE CELLS** 382  
Neurons 383

## 17 Organization and Control of Neural Function 382

**NEUROGLIAL CELLS** 384  
Metabolic Requirements of Nervous Tissue 386  
**NEUROPHYSIOLOGY** 387  
Action Potentials 387  
Synaptic Transmission 388  
**NEUROMUSCULAR JUNCTION** 390  
**DEVELOPMENTAL ORGANIZATION OF THE NERVOUS SYSTEM** 391  
Embryonic Development 392  
Segmentary Organization 394  
**STRUCTURE AND FUNCTION OF THE SPINAL CORD AND BRAIN** 400  
Spinal Cord 400  
The Brain 403  
**THE AUTONOMIC NERVOUS SYSTEM** 413  
Autonomic Efferent Pathways 414  
Sympathetic Nervous System 414  
Parasympathetic Nervous System 416  
Central Integrative Pathways 417  
**AUTONOMIC NEUROTRANSMISSION** 417  
**SOMATIC SENSORY FUNCTION, PAIN, AND HEADACHE** 422  
**ORGANIZATION AND CONTROL OF SOMATOSENSORY FUNCTION** 423  
Sensory Systems 423  
Sensory Modalities 427  
**CLINICAL ASSESSMENT OF SOMATOSENSORY FUNCTION** 429  
**PAIN** 430  
Types of Pain 433  
Management of Pain 439  
**ALTERATIONS IN PAIN SENSITIVITY AND SPECIAL TYPES OF PAIN** 442  
Alterations in Pain Sensitivity 442  
**SPECIFIC TYPES OF PAIN** 443  
**HEADACHE AND ASSOCIATED PAIN** 445  
Headache 445  
Migraine Headache 445  
Cluster Headache 446  
Tension-Type Headache 447  
Chronic Daily Headache 447  
Temporomandibular Joint Pain 448  
**PAIN IN CHILDREN AND OLDER ADULTS** 448  
**PAIN IN CHILDREN** 448  
**PAIN IN OLDER ADULTS** 449  
**DISORDERS OF MOTOR FUNCTION** 452  
**ORGANIZATION AND CONTROL OF MOTOR FUNCTION** 453  
Organization of Movement 453  
The Motor Unit 455  
**SPINAL REFLEXES** 455  
Motor Pathways 457  
Assessment of Motor Function 457  
**DISORDERS OF THE MOTOR UNIT** 461  
Skeletal Muscle Disorders 461  
Disorders of the Neuromuscular Junction 463  
**LOWER MOTOR NEURON DISORDERS** 465  
**PERIPHERAL NERVE DISORDERS** 465  
**DISORDERS OF THE CEREBELLUM AND BASAL GANGLIA** 470  
Disorders of the Cerebellum 470  
Disorders of the Basal Ganglia 471  
**UPPER MOTOR NEURON DISORDERS** 475  
Amyotrophic Lateral Sclerosis 476  
Multiple Sclerosis 476  
Vertebral and Spinal Cord Injury 479
Contents

20 Disorders of Brain Function  489
   MANIFESTATIONS AND MECHANISMS OF
   BRAIN INJURY  489
   Manifestations of Brain Injury  490
   Mechanisms of Brain Injury  493
   TRAUMATIC BRAIN INJURY  502
   Primary and Secondary Brain Injuries  502
   Hematomas  503
   CEREBROVASCULAR DISEASE  506
   Cerebral Circulation  506
   Stroke (Brain Attack)  507
   INFECTIONS AND NEOPLASMS  515
   Infections  515
   Brain Tumors  516
   SEIZURE DISORDERS  519
   Etiology  519
   Classification  520
   Diagnosis and Treatment  521
   Status Epilepticus  522
   Nonconvulsive Seizures  523

21 Sleep and Sleep Disorders  525
   NEUROBIOLOGY OF SLEEP  525
   Neural Structures and Pathways  526
   The Sleep-Wake Cycle  526
   Circadian Rhythms  529
   Melatonin  530
   SLEEP DISORDERS  531
   Diagnostic Methods  531
   Circadian Rhythm Disorders  532
   Insomnia  533
   Narcolepsy  535
   Sleep-Related Movement Disorders  536
   Sleep-Related Breathing Disorders  537
   Parasomnias  539
   SLEEP AND SLEEP DISORDERS IN CHILDREN
   AND OLDER ADULTS  540
   Sleep and Sleep Disorders in Children  540
   Sleep and Sleep Disorders in Older Adults  541

22 Disorders of Thought, Emotion, and
   Memory  544
   PSYCHIATRIC DISORDERS  544
   Incidence and Prevalence  544
   The Diagnosis of Psychiatric Disorders  545
   Understanding Psychiatric Disorders  545
   TYPES OF PSYCHIATRIC DISORDERS  553
   Schizophrenia  553
   Mood Disorders  556
   Anxiety Disorders  559
   Substance Use Disorders  561
   DISORDERS OF MEMORY AND
   COGNITION  562
   Normal Cognitive Aging  562
   Dementia  563

UNIT VI  DISORDERS OF SPECIAL
   SENSORY FUNCTION  573

23 Disorders of Visual Function  574
   DISORDERS OF THE ACCESSORY
   STRUCTURES OF THE EYE  575
   Disorders of the Eyelids  575
   Disorders of the Lacrimal System  577
   DISORDERS OF THE CONJUNCTIVA, CORNEA,
   AND UVEAL TRACT  578
   Disorders of the Conjunctiva  578
   Disorders of the Cornea  581
   Disorders of the Uveal Tract  583
   The Pupil and Pupillary Reflexes  584

UNIT VII  DISORDERS OF THE
   HEMATOPOIETIC SYSTEM  637

25 Blood Cells and the Hematopoietic
   System  638
   COMPOSITION OF BLOOD AND FORMATION
   OF BLOOD CELLS  638
   Plasma  639
   Blood Cells  640
   Formation of Blood Cells
   (Hematopoiesis)  643
   DIAGNOSTIC TESTS  646
   Blood Count  646
   Erythrocyte Sedimentation Rate  646
   Bone Marrow Aspiration and Biopsy  647

26 Disorders of Hemostasis  648
   MECHANISMS OF HEMOSTASIS  648
   Vascular Constriction  649
   Formation of the Platelet Plug  649
   Blood Coagulation  651
   Clot Retraction  652
   Clot Dissolution  652
HYPERCOAGULABILITY STATES  655
Hypercoagulability Associated with Increased Platelet Function  655
Hypercoagulability Associated with Increased Clotting Activity  656
BLEEDING DISORDERS  657
Bleeding Associated with Platelet Disorders  658
Bleeding Associated with Coagulation Factor Deficiencies  660
Bleeding Associated with Vascular Disorders  661
Disseminated Intravascular Coagulation  661

27 Disorders of Red Blood Cells  665
THE RED BLOOD CELL  665
Hemoglobin Synthesis  666
Red Cell Production  667
Red Cell Destruction  668
Red Cell Metabolism and Hemoglobin Oxidation  669
Laboratory Tests  669
BLOOD TYPES AND TRANSfusion THERAPY  671
ABO Blood Groups  671
Rh Types  671
Blood Transfusion Reactions  673
ANEMIA  673
Blood Loss Anemia  674
Hemolytic Anemias  674
Anemias of Deficient Red Cell Production  678
POLycythemia  682
Absolute Polycythemia—Primary  682
Absolute Polycythemia—Secondary  682
AGE-RELATED CHANGES IN RED BLOOD CELLS  683
Red Cell Changes in the Neonate  683
Red Cell Changes With Aging  685

28 Disorders of White Blood Cells and Lymphoid Tissues  688
HEMATopoietic AND LYmphoid TISSUES  688
Leukocytes (White Blood Cells)  689
Bone Marrow and Hematopoiesis  689
Lymphoid Tissues  692
NONNEOplASTIC DISORDERS OF WHITE BLOOD CELLS  693
Neutropenia (Agranulocytosis)  693
Infectious Mononucleosis  696
NEOplASTIC DISORDERS OF LYMPHoid AND HEMATopoietic ORIGIN  697
Malignant Lymphomas  697
Leukemias  701
Plasma Cell Dyscrasias  706

UNIT VIII DISORDERS OF CARDIOVASCULAR FUNCTION  711

29 Structure and Function of the Cardiovascular System  712
ORGANIZATION OF THE CIRCULATORY SYSTEM  712
Pulmonary and Systemic Circulations  713
Volume and Pressure Distribution  714
PRINCIPLES OF BLOOD FLOW  715
Relationships between Blood Flow, Pressure, and Resistance  715

Wall Tension, Radius, and Pressure  718
Distention and Compliance  718
THE HEART AS A PUMP  719
Functional Anatomy of the Heart  719
Cardiac Cycle  723
Regulation of Cardiac Performance  725
THE SYSTEMIC CIRCULATION AND CONTROL OF BLOOD FLOW  727
Blood Vessels  727
Arterial System  728
Venous System  729
Local and Humoral Control of Blood Flow  730
THE MICROCIRCULATION AND LYMPHATIC SYSTEM  732
Structure and Function of the Microcirculation  732
Capillary-Interstitial Fluid Exchange  733
The Lymphatic System  735
NEURAL CONTROL OF CIRCULATORY FUNCTION  735
Autonomic Nervous System Regulation  736
Central Nervous System Responses  737

30 Disorders of Blood Flow in the Systemic Circulation  739
BLOOD VESSEL STRUCTURE AND FUNCTION  740
Endothelial Cells  740
Vascular Smooth Muscle Cells  741
DISORDERS OF THE ARTERIAL CIRCULATION  742
Hyperlipidemia  742
Atherosclerosis  747
Vasculitis  752
Polyarteritis Nodosa  752
Giant Cell Temporal Arteritis  753
Arterial Disease of the Extremities  753
Acute Arterial Occlusion  754
Atherosclerotic Occlusive Disease  754
Thromboangiitis Obliterans  755
Raynaud Disease and Phenomenon  755
Aneurysms  756
Aortic Aneurysms  757
Aortic Dissection  758
DISORDERS OF THE VENOUS CIRCULATION  760
Varicose Veins  761
Venous Thrombosis  762

31 Disorders of Blood Pressure Regulation  766
THE ARTERIAL BLOOD PRESSURE  766
Mechanisms of Blood Pressure Regulation  767
Blood Pressure Measurement  772
HYPERTENSION  773
Primary (Essential) Hypertension  773
Systolic Hypertension  780
Secondary Hypertension  780
Malignant Hypertension  782
High Blood Pressure in Pregnancy  782
High Blood Pressure in Children and Adolescents  784
High Blood Pressure in Older Adults  786
ORTHOSTATIC HYPOTENSION  787
Pathogenesis  787
Etiology  788
Diagnosis  789
Treatment  789
32 Disorders of Cardiac Function 792
   DISORDERS OF THE PERICARDIUM 793
      Acute Pericarditis 794
      Pericardial Effusion and Cardiac Tamponade 795
      Constrictive Pericarditis 796
      CORONARY ARTERY DISEASE 797
      Coronary Circulation 797
      Acute Coronary Syndrome 804
      Chronic Ischemic Heart Disease 812
      CARDIOMYOPATHIES 814
      Primary Cardiomyopathies 814
      Secondary Cardiomyopathies 818
   DISORDERS OF VENTRICULAR FUNCTION 819
      Infective Endocarditis 819
      Rheumatic Heart Disease 821
      VALVULAR HEART DISEASE 824
      Hemodynamic Derangements 824
      Mitral Valve Disorders 824
      Aortic Valve Disorders 827
      HEART DISEASE IN INFANTS AND CHILDREN 829
      Embryonic Development of the Heart 830
      Fetal and Perinatal Circulation 831
      Congenital Heart Defects 832
      Kawasaki Disease 840

33 Disorders of Cardiac Conduction and Rhythm 845
   CARDIAC CONDUCTION SYSTEM 845
      Action Potentials 847
      Electrocardiography 850
      DISORDERS OF CARDIAC RHYTHM AND CONDUCTION 852
      Mechanisms of Arrhythmias and Conduction Disorders 852
      Types of Arrhythmias and Conduction Disorders 853
      Diagnostic Methods 860
      Treatment 861

34 Heart Failure and Circulatory Shock 867
   HEART FAILURE 867
      Pathophysiology of Heart Failure 868
      Acute Heart Failure Syndromes 876
      Clinical Manifestations of Heart Failure 876
      Diagnosis and Treatment 878
      CIRCULATORY FAILURE (SHOCK) 880
      Pathophysiology of Circulatory Shock 882
      Cardiogenic Shock 883
      Hypovolemic Shock 885
      Distributive Shock 887
      Obstructive Shock 889
      Complications of Shock 890
      HEART FAILURE IN CHILDREN AND OLDER ADULTS 891
      Heart Failure in Infants and Children 891
      Heart Failure in Older Adults 893

UNIT IX DISORDERS OF RESPIRATORY FUNCTION 897

35 Structure and Function of the Respiratory System 898
   STRUCTURAL ORGANIZATION OF THE RESPIRATORY SYSTEM 898
   Conducting Airways 900

Lungs and Respiratory Airways 904
Pulmonary Vasculature and Lymphatic Supply 905
Innervation 906
Pleura 908
EXCHANGE OF GASES BETWEEN THE ATMOSPHERE AND THE LUNGS 908
Basic Properties of Gases 908
Ventilation and the Mechanics of Breathing 908
Lung Volumes 913
Pulmonary Function Studies 914
Efficiency and the Work of Breathing 915
EXCHANGE AND TRANSPORT OF GASES 916
Ventilation 916
Perfusion 917
Mismatching of Ventilation and Perfusion 918
Diffusion 919
Oxygen and Carbon Dioxide Transport 919
CONTROL OF BREATHING 924
Respiratory Center 924
Regulation of Breathing 924
Cough Reflex 926
Dyspnea 926

36 Respiratory Tract Infections, Neoplasms, and Childhood Disorders 928
   RESPIRATORY TRACT INFECTIONS 929
      The Common Cold 929
      Rhinosinusitis 930
      Influenza 932
      Pneumonias 934
      Tuberculosis 939
      Fungal Infections 942
      CANCER OF THE LUNG 945
      Histologic Subtypes and Pathogenesis 945
      Clinical Manifestations 947
      Diagnosis and Treatment 947
      RESPIRATORY DISORDERS IN CHILDREN 948
      Lung Development 948
      Manifestations of Respiratory Disorders or Infection in the Infant or Small Child 951
      Respiratory Disorders in the Neonate 951
      Respiratory Infections in Children 952

37 Disorders of Ventilation and Gas Exchange 958
   PHYSIOLOGIC EFFECTS OF VENTILATION AND DIFFUSION DISORDERS 959
   Hypoxemia 959
   Hypocapnia 962
   DISORDERS OF LUNG INFLATION 963
   Disorders of the Pleura 963
   Atelectasis 967
   OBSTRUCTIVE AIRWAY DISORDERS 968
   Physiology of Airway Disease 968
   Asthma 969
   Chronic Obstructive Pulmonary Disease 973
   Bronchiectasis 977
   Cystic Fibrosis 978
   CHRONIC INTERSTITIAL (RESTRICTIVE) LUNG DISEASES 981
   Etiology and Pathogenesis of Interstitial Lung Diseases 981
   Clinical Manifestations 981
   Diagnosis and Treatment 982
UNIT X  DISORDERS OF RENAL FUNCTION AND FLUIDS AND ELECTROLYTES 997

38 Structure and Function of the Kidney 998

KIDNEY STRUCTURE AND FUNCTION 998
Gross Structure and Location 998
Renal Blood Supply 1000
The Nephron 1000
Urinary Formation 1003
Regulation of Renal Blood Flow 1008
Elimination Functions of the Kidney 1010
Endocrine Functions of the Kidney 1012
Action of Diuretics 1013
TESTS OF RENAL FUNCTION 1015
Urinary Tests 1015
Glomerular Filtration Rate 1016
Blood Tests 1016
Cystoscopy 1017
Ultrasonography 1017
Radiologic and Other Imaging Studies 1017

39 Disorders of Fluid and Electrolyte Balance 1019

COMPOSITION AND COMPARTMENTAL DISTRIBUTION OF BODY FLUIDS 1019
Dissociation of Electrolytes 1020
Diffusion and Osmosis 1020
Compartmental Distribution of Body Fluids 1022
Capillary–Interstitial Fluid Exchange 1023
SODIUM AND WATER BALANCE 1028
Body Water Balance 1028
Sodium Balance 1029
Mechanisms of Regulation 1030
Thirst and Antidiuretic Hormone 1030
Disorders of Sodium and Water Balance 1033
POTASSIUM BALANCE 1041
Regulation of Potassium Balance 1041
Disorders of Potassium Balance 1042
CALCIUM, PHOSPHORUS, AND MAGNESIUM BALANCE 1047
Mechanisms Regulating Calcium, Phosphorus, and Magnesium Balance 1047
Disorders of Calcium Balance 1050
Disorders of Phosphorus Balance 1054
Disorders of Magnesium Balance 1056

40 Disorders of Acid–Base Balance 1062

MECHANISMS OF ACID–BASE BALANCE 1062
Acid–Base Chemistry 1062
Metabolic Acid and Bicarbonate Production 1063
Calculation of pH 1065

41 Disorders of Renal Function 1083

CONGENITAL AND INHERITED DISORDERS OF THE KIDNEYS 1084
Congenital Disorders of the Kidneys 1084
Inherited Cystic Kidney Diseases 1084
Simple and Acquired Renal Cysts 1087
OBSTRUCTIVE DISORDERS 1088
Mechanisms of Renal Damage 1089
Renal Calculi 1090
URINARY TRACT INFECTIONS 1093
Etiology and Pathogenesis 1094
Clinical Manifestations 1095

### Examples

- **anemia** (lack of blood)
- **adductor** (leading away from)
- **anaclitic** (type of glandular secretion)
- **anaesthetic** (against coagulation)
- **anticoagulant** (opposing coagulation)
- **aseptic** (against infection)
- **enucleate** (removal of the eye)
semi- half, partly
semiflexion (a limb midway between flexion and extension)
semimembranous (composed in part of membrane)
steno- narrow compressed, contracted
stenocoriais (contraction of the pupil of the eye)
stenopeic (having a narrow slit or opening)
sub-, sup- under, below
subarachnoid (under arachnoid)
subcutaneous (under skin)
supra- above, beyond, extreme
supermedial (above the middle)
supernumerary (an extreme number)
suprarenal (above kidney)
suprascapular (on upper part of the scapula)
sym- sym- together, with
symphysis (joining together)
tachy- swift, rapid
tachycardia (rapid action of the heart)
tachyrothymia (rapid metabolism)
trans- across, through, beyond
transection (cut across)
transduodenal (through the duodenum)
ultra- beyond, in excess
ultraligation (ligation of vessel beyond point of origin)
ultrasonic (sound waves above the human ear’s audibility limit)

-SUFFIXES-

-able, -ible ability to, capable of
viabile (capable of living)
-al, -ar pertaining to
labial (pertaining to the lip or lips)
ocular (pertaining to the eye)
alalgia a painful condition
neuralgia (pain that affects nerves)
ary pertaining to, connected with
ciliary (resembling a hairlike structure)
ovary (connected with the ovum)
at- action or state
degenerate (to decline in condition)
hemolysate (product of hemolysis)
cle-, -cula, -cule, -culum, -culus diminutive
cerebellum (little brain)
molecule (small physical unit)
pedicle (small footlike part)

-ectasia, -ectasis a dilated or distended state
bronchiectasis (dilatation of the bronchi)
lymphectasia (distention with lymph)
etectomy cutting out
appendectomy (excision of the appendix)
esthesia condition of sensation
somatesthesia (somatic sense)
-form shape, structure
multiform (occurring in many shapes)
ossiform (resembling the structure of bones)
fugal moving away from, driving away
centrifugal (moving away from a center)
febrifugal (relieving fever)
gen- genic producing, produced by
allergen (allergy producing)
carcinogenic (cancer-producing agent)
gram a record, writing
electrocardiogram (the graphic record of an electrocardiograph)
mammogram (an x-ray film of breast tissue)
-ia state, condition
amblyopia (dimness of vision)
septicaemia (poisoning of the blood)
iceptic (pertaining to madness)
orchic (pertaining to the testes)
ile pertaining to, characteristics of
febrile (pertaining to fever)
infantile (characteristic of infants)
-ion process, action
flexion (act of bending)
hydration (the act of combining with water)
-ism condition, state
astigmatism (defect of vision due to corneal irregularity)
rheumatism (inflammation, typically of muscles and joints)
-itis inflammation
appendicitis (inflammation of the appendix)
carditis (inflammation of the heart muscles)
-ity state
disparity (inequality)
hyperacidity (state characterized by the presence of excess acid)
-logy a collected body of knowledge
biology (the branch of knowledge that deals with living organisms)
pathology (the study of characteristics, causes, and effects of disease)
-lysis disintegration, dissolution
 cytolysis (cell destruction)
hemolysis (the dissolution of red blood cells)
-odyne, odyinia pain, referring to/location of pain
gastrodynia (stomach pain)
odontodynia (toothache)
oid resembling, like
epidermoid (resembling epidermis)
thyroid (shaped like a shield)
-ole, -ulus diminutive
centriole (a small center)
malleolus (a small hammer)
or agent
donor (one who donates)
levator (an agent that elevates)
-penia a deficiency
leukopenia (deficiency of white blood cells)
thrombocytopenia (deficiency of thrombocytes)
-phagia, -phagy ingestion of, consumption of, practice of eating of a substance
geophagia (eating earthy substances)
lipophagia (ingestion of fat by cells)
-plegia a paralyzed state
esophagoplegia (paralysis of the esophagus)
hemiplegia (paralysis of one side of the body)
-poiesis formation of, production of
cholanopoiesis (production of bile acids)
hepatopoiesis (formation of red blood cells)
-ptosis downward displacement, prolapse
enteroptosis (downward displacement of the intestine)
hepatoptosis (displacement of the liver)
rhagia a breaking forth, bursting, fluid discharge
lymphorrhagia (a flow of lymph)
tracheorrhagia (bleeding from the trachea)
rhaphy a suturing in place
cystorrhaphy (suturing the bladder)
gastrorrhaphy (surgical suture of the stomach)
rhhea flow
diarrhea (abnormally frequent intestinal evacuations)
laryngorrhoea (excessive mucus flow whenever the voice is used)
tomy cut into, incision into
phlebotomy (incision of a vein)
tracheotomy (cutting into the trachea)
sis (-asis, -esis, -osis) state or process
dermatosis (a skin disease)
hematemesis (vomiting blood)
Mrs. Sora, 85 years old, was born during the Great Depression. She is a widow who has recently moved in with her daughter since her social security income was not enough to allow her to keep her own home. She presents with soreness and back pain, describing “a tingling and burning feeling on the left side of my back just above my waist.” The discomfort started about 2 days ago, and she thought it would go away. However, it has increased in intensity, and this morning she noticed a rash over the painful region.

Her daughter suspects that her mother’s vision has declined, because she has had a few recent falls in the evenings. The daughter is also concerned about her mother’s loss of hearing acuity and appetite and her growing fatigue. The daughter adds that her mom was hospitalized for pneumonia about 4 months ago, and became very confused during the course of the illness.

Mrs. Sora’s vital signs are all within normal limits (blood pressure = 122/68 mm Hg, pulse = 77, respiratory rate = 14/minute, and temperature = 98.8°F). Physical examination of the rash on Mrs. Sora’s back reveals grouped vesicular papules over the T7 left side dermatome. Discomfort is felt with light palpation. Upon further questioning Mrs. Sora says, “Yes, I had chicken pox when I was in first grade.” The rash is diagnosed as varicella-zoster virus (VZV). Mrs. Sora’s case is discussed further in Chapter 3 along with her daughter’s other concerns.
The term *pathophysiology*, which is the focus of this book, may be defined as the physiology of altered health. The term combines the words *pathology* and *physiology*. Pathology (from the Greek *pathos*, meaning “disease”) deals with the study of the structural and functional changes in cells, tissues, and organs of the body that cause or are caused by disease. Physiology deals with the functions of the human body. Thus, pathophysiology deals not only with the cellular and organ changes that occur with disease but with the effects that these changes have on total body function (Fig. 1.1). Examples of atrophy of the brain (Fig. 1.1A) and hypertrophy of the myocardium (Fig. 1.1B) illustrate pathophysiological changes from a cerebrovascular accident to long-standing unmanaged hypertension and how this impacts the myocardium. Pathophysiology also focuses on the mechanisms of the underlying disease and provides information to assist with planning preventive as well as therapeutic health care measures and practices such as following a healthy diet, exercising, and being compliant with prescribed medications. This chapter is intended to orient the reader to the concepts of health and disease, various terms that are used throughout the book, the sources of data and what they mean, and the broader aspects of pathophysiology in terms of the health and well-being of populations.
What constitutes health and disease often is difficult to determine because of the way different people view the topic. What is defined as health is determined by many factors, including genetics, age, gender, cultural, and ethnic differences, as well as individual, group, and governmental expectations.

**Health**

In 1948, the Preamble to the Constitution of the World Health Organization (WHO) defined health as a “state of complete physical, mental, and social well-being and not merely the absence of disease and infirmity,” a definition that has not been amended since that time. Although ideal for many people, this was an unrealistic goal. The U.S. Department of Health and Human Services in *Healthy People 2020* describes the determinants of health as

1. Attain lives free of preventable disease, disability, injury, and premature death
2. Achieve health equity and eliminate disparities
3. Promote good health for all
4. Promote healthy behaviors across the life span

Every decade, the U.S. Department of Health and Human Services spearheads initiatives to facilitate the goals of the new decade in their report such as the current *Healthy People 2020*. These consensus reports are developed to specifically assist in preventing some health problems and to offer advice to promote health as defined by the WHO.

**Disease**

A disease is considered an acute or chronic illness that one acquires or is born with that causes physiological dysfunction in one or more body system. Each disease generally has specific signs and symptoms that characterize its pathology and identifiable etiology. The aspects of the disease process include etiology, pathogenesis, morphologic changes, clinical manifestations, diagnosis, and clinical course.

**Etiology**

The causes of disease are known as *etiologic factors*. Among the recognized etiologic agents are biologic agents (*e.g.*, bacteria, viruses), physical forces (*e.g.*, trauma, burns, radiation), chemical agents (*e.g.*, poisons, alcohol), one’s genetic inheritance, and nutritional excesses or deficits.

Most disease-causing agents are nonspecific, and many different agents can cause disease of a single organ. On the other hand, a single agent or traumatic event can lead to disease of a number of organs or systems. For example, in cystic fibrosis, sickle cell anemia, and familial hypercholesterolemia, a single amino acid, transporter molecule, or receptor protein produces widespread pathology. Although a disease agent can affect more than a single organ and a number of disease agents can affect the same organ, most disease states do not have a single cause. Instead, the majority of diseases are multifactorial in origin. This is particularly true of diseases such as cancer, heart disease, and diabetes. This is illustrated in Figure 1.2, which traces the five causes of cancer and the pathophysiology that evolves from the disease mechanisms triggered by the causes. The multiple factors that predispose to a particular disease often are referred to as *risk factors*.

One way to view the factors that cause disease is to group them into categories according to whether they were present at birth or acquired later in life. *Congenital conditions* are defects that are present at birth, although they may not be evident until later in life or may never manifest. Congenital conditions may be caused by genetic influences, environmental factors (*e.g.*, viral infections in the mother, maternal drug use, irradiation, or gestational position in utero), or a combination of genetic and environmental factors. *Acquired defects* are those that are caused by events that occur after birth. These include injury,
This will assist in identifying etiology of disease and in the development of individualized interventions.

Pathogenesis

While etiology describes what sets the disease process in motion, pathogenesis explains how the disease process evolves. In other words, pathogenesis is the sequence of cellular and tissue events that take place from the time of initial contact with an etiologic agent until the ultimate expression of a disease. Although etiology and pathogenesis are two terms often used interchangeably, their meanings are quite different. For example, atherosclerosis often is cited as the etiology (or cause) of coronary artery disease. In reality, the progression of the inflammatory process from a fatty streak to the occlusive vessel lesion seen in people with coronary artery disease represents the pathogenesis of the disorder. The true etiology of atherosclerosis remains largely uncertain.

Morphology and Histology

Morphology refers to the fundamental structure or form of cells or tissues. Morphologic changes are concerned with both the gross anatomic and microscopic changes that are characteristic of a disease. Histology deals with the study of the cells and extracellular matrix of body tissues. The most common method used in the study of tissues is the preparation of histologic sections—thin, translucent sections of human tissues and organs—that can be examined with the aid of a microscope. Histologic sections play an important role in the diagnosis of many types of cancer.

A lesion represents a pathologic or traumatic discontinuity of a body organ or tissue. Descriptions of lesion size and characteristics often can be obtained through the use of radiographs, ultrasonography, and other imaging methods. Lesions also may be sampled by biopsy and the tissue samples subjected to histologic study. Diagnostic pathology has evolved greatly in the last few years to include immunologic and molecular biological tools for studying disease states (Fig. 1.3).

Clinical Manifestations

Diseases can manifest in a number of ways. Sometimes the condition produces manifestations, such as fever, that make it evident that the person is sick. In other cases, the condition is silent at the onset and is detected during examination for other purposes or after the disease is far advanced.

Signs and symptoms are terms used to describe the structural and functional changes that accompany a disease. A symptom is a subjective complaint that is noted by the person with a disorder, whereas a sign is a manifestation that is noted by an observer. Pain, difficulty in breathing, and dizziness are symptoms of a disease. An elevated temperature, a swollen extremity, and changes in pupil size are objective signs that can be observed by someone other than the person with the disease. Signs and symptoms may be related to the primary disorder or they may represent the body’s attempt to compensate for the altered function caused by the pathologic condition. Many pathologic states are not observed directly. For example, one cannot see that a person is hemorrhaging or that he or she

exposure to infectious agents, inadequate nutrition, lack of oxygen, inappropriate immune responses, and neoplasia. Many diseases are thought to be the result of a genetic predisposition and an environmental event or events that serve as a trigger to initiate disease development. There are 35,000 genes in the human genome, 1 to 10 million proteins, and 2 to 3000 metabolites of the human metabolome. Huge advances in molecular biology and the wide variability of people have led to evolution in systems biology and personalized medicine.

clinical presentation. The clinical probability of a given disease in a person of a given age, gender, race, lifestyle, genetic background, and locality often is influential in arriving at a presumptive diagnosis. Laboratory tests and imaging are used to confirm a diagnosis.

An important factor when interpreting diagnostic test results is the determination of whether they are normal or abnormal. Is a blood count above normal, within the normal range, or below normal? What is termed a normal value for a laboratory test is established statistically from test results obtained from a selected sample of people. A normal value represents the test results that fall within the bell curve or the 95% distribution. Thus, the normal levels for serum sodium (136 to 145 mEq/L) represent the mean serum level for the reference population ±2 standard deviations. The normal values for some laboratory tests are adjusted for gender, other comorbidities, or age. For example, the normal hemoglobin range for women is 12.0 to 16.0 g/dL, and for men, 14.0 to 17.4 g/dL. Serum creatinine level often is adjusted for age in the elderly, and normal values for serum phosphate differ between adults and children.

Laboratory parameters are interpreted based on the reliability, validity, sensitivity, and specificity of the measurement. Validity refers to the extent to which a measurement tool measures what it is intended to measure. For example, the validity of blood pressure measurements obtained by a sphygmomanometer might be compared with those obtained

![Figure 1.3](image-url)
by intra-arterial findings, which are measurements obtained from invasive arterial catheters inserted into radial arteries of acutely ill people. Reliability refers to the extent to which an observation, if repeated, gives the same result. A poorly calibrated blood pressure machine may give inconsistent measurements of blood pressure, particularly of pressures in either the high or low range. Reliability also depends on the person’s skill in taking the measurements. For example, blood pressure measurements may vary from one person to another because of the technique that is used (e.g., different observers may deflate the cuff at a different rate, thus obtaining different values), the way the numbers on the manometer are read, or differences in hearing acuity.

In the field of clinical laboratory measurements, standardization is aimed at increasing the trueness and reliability of measured values. Standardization relies on the use of written standards, reference measurement procedures, and reference materials. In the United States, the Food and Drug Administration (FDA) regulates in vitro diagnostic devices, including clinical laboratory instruments, test kits, and reagents. Manufacturers who propose to market new diagnostic devices must submit information on their instrument, test kit, or reagent to the FDA, as required by existing statutes and regulations. The FDA reviews this information to decide whether the product may be marketed in the United States.

Measures of sensitivity and specificity are concerned with determining how likely or how well the test or observation will identify people with the disease and people without the disease (Fig. 1.4). Sensitivity refers to the proportion of people with a disease who are positive for that disease on a given test or observation (called a true-positive result). If the result of a very sensitive test is negative, it tells us the person does not have the disease and the disease has been excluded or “ruled out.” Specificity refers to the proportion of people without the disease who are negative on a given test or observation (called a true-negative result). Specificity can be calculated only from among people who do not have the disease. A test that is 95% specific correctly identifies 95 of 100 normal people. The other 5% are false-positive results. A false-positive test result can be unduly stressful for the person being tested, whereas a false-negative test result can delay diagnosis and jeopardize the outcome of treatment.

Predictive value is the extent to which an observation or test result is able to predict the presence of a given disease or condition. A positive predictive value refers to the proportion of true-positive results that occurs in a given population. In a group of women found to have “suspect breast nodules” in a cancer screening program, the proportion later determined to have breast cancer would constitute the positive predictive value. A negative predictive value refers to the true-negative observations in a population. In a screening test for breast cancer, the negative predictive value represents the proportion of women without suspect nodules who do not have breast cancer. Although predictive values rely in part on sensitivity and specificity, they depend more heavily on the prevalence of the condition in the population. Despite unchanging sensitivity and specificity, the positive predictive value of an observation rises with prevalence, whereas the negative predictive value falls.

Clinical Course
The clinical course describes the evolution of a disease. A disease can have an acute, subacute, or chronic course. An acute disorder is one that is relatively severe, but self-limiting. Chronic disease implies a continuous, long-term process. A chronic disease can run a continuous course or can present with exacerbations (aggravation of symptoms and severity of the disease) and remissions (a period during which there is a decrease in severity and symptoms). Subacute disease is intermediate or between acute and chronic. It is not as severe as an acute disease and not as prolonged as a chronic disease.

The spectrum of disease severity for infectious diseases, such as hepatitis B, can range from preclinical to persistent chronic infection. During the preclinical stage, the disease is not clinically evident but is destined to progress to clinical disease. As with hepatitis B, it is possible to transmit a virus during the preclinical stage. Subclinical disease is not clinically apparent and is not destined to become clinically apparent. It is diagnosed with antibody or culture tests. Most cases of tuberculosis are not clinically apparent, and evidence of their presence is established by skin tests. Clinical disease is manifested by signs and symptoms. A persistent chronic infectious disease persists for years, sometimes for life. Carrier status refers to a person who harbors an organism but is not infected, as evidenced by antibody response or clinical manifestations. This person still can infect others. Carrier status may be of limited duration or it may be chronic, lasting for months or years.

### FIGURE 1.4

The relationship between a diagnostic test result and the occurrence of disease. There are two possibilities for the test result to be correct (true positive and true negative) and two possibilities for the result to be incorrect (false positive and false negative). **IN SUMMARY**

The term pathophysiology, which is the focus of this book, may be defined as the physiology of altered health. A disease has been defined as any deviation from or interruption of the...
normal structure or function of any part, organ, or system of
the body that is manifested by a characteristic set of symp-
toms or signs and whose etiology, pathology, and prognosis
may be known or unknown. The causes of disease are known
as etiologic factors. Pathogenesis describes how the disease
process evolves. Morphology refers to the structure or form of
cells or tissues; morphologic changes are changes in structure
or form that are characteristic of a disease.

A disease can manifest in a number of ways. A symptom
is a subjective complaint, such as pain or dizziness, whereas
a sign is an observable manifestation, such as an elevated
temperature or a reddened, sore throat. A syndrome is a
compilation of signs and symptoms that are characteristic
of a specific disease state.

A diagnosis is the designation as to the nature and cause
of a health problem. Health care providers need to perform
comprehensive histories and PEs and validate their findings
with diagnostic tests, including laboratory tests, imaging
studies (e.g., CT scans), and other tests. The value of many
diagnostic tests is based on their reliability and validity, as
well as their sensitivity and specificity. Having a compre-
prehensive understanding of pathophysiology will assist the
health care provider to best identify problems during the his-
tory and PE and to use laboratory data as further validation.

The clinical course of a disease describes its evolution.
It can be acute (relatively severe, but self-limiting), chronic
(continuous or episodic, but taking place over a long
period), or subacute (not as severe as acute or as prolonged
as chronic). Within the disease spectrum, a disease can be
designated preclinical, or not clinically evident; subclinical,
not clinically apparent and not destined to become clinically
apparent; or clinical, characterized by signs and symptoms.

**Epidemiology and Patterns of Disease**

Epidemiology is the study of disease occurrence in human popu-
lations. It was initially developed to explain the spread of infectious
diseases during epidemics and has emerged as a science to study
risk factors for multifactorial diseases, such as heart disease and
cancer. Epidemiology looks for patterns of people affected with
a particular disorder, such as age, race, dietary habits, lifestyle, or
geographic location. In contrast to biomedical researchers who
study the mechanisms of disease production, epidemiologists
are more concerned with whether something happens than how
it happens. For example, the epidemiologist is more concerned
with whether smoking itself is related to cardiovascular disease
and whether the risk of heart disease decreases when smoking
cesses. On the other hand, the biomedical researcher is more
concerned about the causative agent in cigarette smoke and the
pathway by which it contributes to heart disease.

Much of our knowledge about disease comes from epide-
mologic studies. Epidemiologic methods are used to determine
how a disease is spread, how to control it, how to prevent it,
and how to eliminate it. Epidemiologic methods also are used
to study the natural history of disease, to evaluate new preven-
tive and treatment strategies, to explore the impact of differ-
et patterns of health care delivery, and to predict future health
care needs. As such, epidemiologic studies serve as a basis for
clinical decision making, allocation of health care dollars, and
development of policies related to public health issues.

**Incidence and Prevalence**

Measures of disease frequency are an important aspect of epi-
demiology. They establish a means for predicting what diseases
are present in a population and provide an indication of the
rate at which they are increasing or decreasing. A disease case
can be either an existing case or the number of new episodes
of a particular illness that is diagnosed within a given period.
Incidence reflects the number of new cases arising in a popula-
tion at risk during a specified time. The population at risk is
considered to be people without the disease but who are at risk
for developing it. It is determined by dividing the number of
new cases of a disease by the population at risk for develop-
ment of the disease during the same period (e.g., new cases per
1000 or 100,000 people in the population who are at risk). The
cumulative incidence estimates the risk of developing the disease
during that period of time. Prevalence is a measure of existing
disease in a population at a given point in time (e.g., number of
existing cases divided by the current population). The preva-
lence is not an estimate of risk of developing a disease because
it is a function of both new cases and how long the cases remain
in the population. Incidence and prevalence are always reported
as rates (e.g., cases per 100 or cases per 100,000).
Morbidity and Mortality

Morbidity and mortality statistics provide information about the functional effects (morbidity) and death-producing (mortality) characteristics of a disease. These statistics are useful in terms of anticipating health care needs, planning of public education programs, directing health research efforts, and allocating health care dollars.

Morbidity describes the effects an illness has on a person’s life. Many diseases, such as arthritis, have low death rates but a significant impact on a person’s life. Morbidity is concerned not only with the occurrence or incidence of a disease but with persistence and the long-term consequences of the disease.

Mortality statistics provide information about the causes of death in a given population. In most countries, people are legally required to record certain facts such as age, gender, and cause of death on a death certificate. Internationally agreed on classification procedures (the International Classification of Diseases [ICD] by the WHO) are used for coding the cause of death, and the data are expressed as death rates. Crude mortality rates (i.e., number of deaths in a given period) do not account for age, gender, race, socioeconomic status, and other factors. For this reason, mortality often is expressed as death rates for a specific population, such as the infant mortality rate. Mortality also can be described in terms of the leading causes of death according to age, gender, race, and ethnicity. For example, among all people 65 years of age and older, the five leading causes of death in the United States are heart disease, cerebrovascular disease, malignant disease, chronic lower respiratory disease, and accidents.

Determination of Risk Factors

Conditions suspected of contributing to the development of a disease are called risk factors. They may be inherent to the person (high blood pressure or overweight) or external (smoking or drinking alcohol). There are different types of studies used to determine risk factors, including cross-sectional studies, case–control studies, and cohort studies.

Cross-Sectional and Case–Control Studies

Cross-sectional studies use the simultaneous collection of information necessary for classification of exposure and outcome status. They can be used to compare the prevalence of a disease in those with the factor (or exposure) with the prevalence of a disease in those who are unexposed to the factor, for example, by comparing the prevalence of coronary heart disease in smokers and nonsmokers. Case–control studies are designed to compare people known to have the outcome of interest (cases) and those known not to have the outcome of interest (controls). Information on exposures or characteristics of interest is then collected from people in both groups. For example, the characteristics of maternal alcohol consumption in infants born with fetal alcohol syndrome (cases) can be compared with those in infants born without the syndrome (controls).

Cohort Studies

A cohort is a group of people who were born at approximately the same time or share some characteristics of interest. People enrolled in a cohort study (also called a longitudinal study) are followed over a period of time to observe a specific health outcome. A cohort may consist of a single group of people chosen because they have or have not been exposed to suspected risk factors. For example, two groups specifically selected because one has been exposed and the other has not or a single exposed group in which the results are compared with the general population.

Framingham Study. One of the best-known examples of a cohort study is the Framingham Study, which was carried out in Framingham, Massachusetts. Framingham was selected because of the size of the population, the relative ease with which the people could be contacted, and the stability of the population in terms of moving into and out of the area. This longitudinal study, which began in 1950, was set up by the U.S. Public Health Service to study the characteristics of people who would later develop coronary heart disease. The study consisted of 5000 persons, between 30 and 59 years of age, selected at random and followed for an initial period of 20 years. During this time it was predicted that 1500 of them would develop coronary heart disease. The advantage of such a study is that it can explore a number of risk factors at the same time and determine the relative importance of each. Another advantage is that the risk factors can be related later to other diseases such as stroke.

Nurses’ Health Study. Another well-known cohort study is the Nurses’ Health Study, which was developed by Harvard University and Brigham and Women’s Hospital. The study began in 1976 with a cohort of 121,700 female nurses, 30 to 55 years of age, living in the United States. The study expanded in 1989 to include a group of 238,000 female nurse participants. Initially designed to explore the relationship between oral contraceptives and breast cancer, nurses in the study have provided answers to detailed questions about their menstrual cycle, smoking habits, diet, weight and waist measurements, activity patterns, health problems, and medication use. They have collected urine and blood samples and even provided researchers with their toenail clippings. In selecting the cohort, it was reasoned that nurses would be well organized, accurate, and observant in their responses and that physiologically they would be no different from other groups of women. It also was anticipated that their childbearing, eating, and smoking patterns would be similar to those of other working women.

Natural History

The natural history of a disease refers to the progression and projected outcome of the disease without medical intervention. By studying the patterns of a disease over time in populations, epidemiologists can better understand its natural history. Knowledge of the natural history can be used to determine disease outcome, establish priorities for health care services, determine the effects of screening and early detection programs on disease outcome, and compare the results of new treatments with the expected outcome without treatment.

There are some diseases for which there are no effective treatment methods available, or the current treatment measures...
are effective only in certain people. In this case, the natural history of the disease can be used as a predictor of outcome. For example, the natural history of hepatitis C indicates that 80% of people who become infected with the virus fail to clear the virus and progress to chronic infection. Information about the natural history of a disease and the availability of effective treatment methods provides directions for preventive measures. In the case of hepatitis C, careful screening of blood donations and education of intravenous drug abusers can be used to prevent transfer of the virus. At the same time, scientists are striving to develop a vaccine that will prevent infection in people exposed to the virus. The development of vaccines to prevent the spread of infectious diseases such as polio and hepatitis B undoubtedly has been motivated by knowledge about the natural history of these diseases and the lack of effective intervention measures. With other diseases, such as breast cancer, early detection through use of breast self-examination and mammography increases the chances for a cure.

**Prognosis** refers to the probable outcome and prospect of recovery from a disease. It can be designated as chances for full recovery, possibility of complications, or anticipated survival time. Prognosis often is presented in relation to treatment options, that is, the expected outcomes or chances for survival with or without a certain type of treatment. The prognosis associated with a given type of treatment usually is presented along with the risk associated with the treatment.

### Preventing Disease

Basically, leading a healthy life contributes to the prevention of disease. There are three fundamental types of prevention—primary prevention, secondary prevention, and tertiary prevention (Fig. 1.5). It is important to note that all three levels are aimed at prevention.

**Primary prevention** is directed at keeping disease from occurring by removing all risk factors. Examples of primary prevention include the administration of folic acid to pregnant women and women who may become pregnant to prevent neural tube defects, giving immunizations to children to prevent communicable disease, and counseling people to adopt healthy lifestyles as a means of preventing heart disease. Primary prevention is often accomplished outside the health care system at the community level. Some primary prevention measures are mandated by law (e.g., wearing seat belts in automobiles and helmet use on motorcycles). Other primary prevention activities (e.g., use of earplugs or dust masks) occur in specific occupations.

**Secondary prevention** detects disease early when it is still asymptomatic and treatment measures can effect a cure or stop the disease from progressing. The use of a Papanicolaou (Pap) smear for early detection of cervical cancer is an example of secondary prevention. Screening also includes history taking (asking if a person smokes), PE (blood pressure measurement), laboratory tests (cholesterol level determination), and other procedures (colonoscopy) that can be "applied reasonably rapidly to asymptomatic people." Most secondary prevention is done in clinical settings. All types of health care professionals (e.g., physicians, nurses, dentists, audiologists, optometrists) participate in secondary prevention.

**Tertiary prevention** is directed at clinical interventions that prevent further deterioration or reduce the complications of a disease once it has been diagnosed. An example is the use of β-adrenergic drugs to reduce the risk of death in people who have had a heart attack. The boundaries of tertiary prevention go beyond treating the problem with which the person presents. In people with diabetes, for example, tertiary prevention requires more than good glucose control. It also includes provision for regular ophthalmologic examinations for early detection of retinopathy, education for good foot care, and treatment for other cardiovascular risk factors such as hyperlipidemia. Tertiary prevention measures also include measures to limit physical impairment and the social consequences of an illness. Most tertiary prevention programs are located within health care systems and involve the services of a number of different types of health care professionals.

### Evidence-Based Practice and Practice Guidelines

Evidence-based practice and evidence-based practice guidelines have gained popularity with clinicians, public health practitioners, health care organizations, and the public as a means of improving the quality and efficiency of health care. Their development has been prompted, at least in part, by the enormous amount of published information about diagnostic and treatment measures for various disease conditions as well as demands for better and more cost-effective health care.

**Evidence-based practice** refers to making decisions in health care based on scientific data that has shown a specific way of managing a disease, patient symptoms, and complaints. Using evidence-based practice mandates that health care providers cannot practice according to only "their" way or according to "how it has always been done before." Evidence-based practice is based on the integration of the individual clinical expertise of the practitioner with the best external clinical evidence from systematic research.

The term **clinical expertise** implies the proficiency and judgment that individual clinicians gain through clinical experience and clinical practice. The best external clinical evidence relies on the identification of clinically relevant research, often from the basic sciences, but especially from patient-centered
Clinical studies that focus on the accuracy and precision of diagnostic tests and methods, the power of prognostic indicators, and the effectiveness and safety of therapeutic, rehabilitative, and preventive regimens.

Clinical practice guidelines are systematically developed statements intended to inform practitioners and people in making decisions about health care for specific clinical circumstances. Providers not only should review but must weigh various outcomes, both positive and negative, and make recommendations. Guidelines are different from systematic reviews. They can take the form of algorithms, which are step-by-step methods for solving a problem, written directives for care, or a combination thereof.

The development of evidence-based practice guidelines often uses methods such as meta-analysis to combine evidence from different studies to produce a more precise estimate of the accuracy of a diagnostic method or the effects of an intervention method. Development of evidence-based practice guidelines requires review. Those who should review the guidelines include practitioners with expertise in clinical content, who can verify the completeness of the literature review and ensure clinical sensibility; experts in guideline development who can examine the method by which the guideline was developed; and potential users of the guideline.

Once developed, practice guidelines must be continually reviewed and changed to keep pace with new research findings and new diagnostic and treatment methods. For example, both the Guidelines for the Prevention, Evaluation, and Treatment of High Blood Pressure, first developed in 1972 by the Joint National Committee, and the Guidelines for the Diagnosis and Management of Asthma, first developed in 1991 by the Expert Panel, have undergone multiple revisions as new evidence from research has evolved.

Evidence-based practice guidelines, which are intended to direct patient care, are also important in directing research into the best methods of diagnosing and treating specific health problems. For example, health care providers use the same criteria for diagnosing the extent and severity of a particular condition such as hypertension with the proven guidelines for hypertension (The 7th Report of the Joint National Committee on Prevention, Detection, and Evaluation, and Treatment of High Blood Pressure [JNC 7]). Providers also use the same protocols for treatment with their hypertension patients until new data supports a change such as the use of new pharmacological agents.

Who have a particular disease at a given point in time or period. Incidence and prevalence are reported as proportions or rates (e.g., cases per 100 or 100,000 population). Morbidity describes the effects an illness has on a person’s life. It is concerned with the incidence of disease as well as its persistence and long-term consequences. Mortality, or death, statistics provide information about the causes of death in a given population.

Conditions suspected of contributing to the development of a disease are called risk factors. Studies used to determine risk factors include cross-sectional studies, case–control studies, and cohort studies. The natural history refers to the progression and projected outcome of a disease without medical intervention. Prognosis is the term used to designate the probable outcome and prospect of recovery from a disease.

The three fundamental types of prevention are primary prevention, secondary prevention, and tertiary prevention. Primary prevention, such as immunizations, is directed at removing risk factors so disease does not occur. Secondary prevention, such as a Pap smear, detects disease when it still is asymptomatic and curable with treatment. Tertiary prevention, such as use of β-adrenergic drugs to reduce the risk of death in persons who have had a heart attack, focuses on clinical interventions that prevent further deterioration or reduce the complications of a disease.

Evidence-based practice and evidence-based practice guidelines are mechanisms that use the current best evidence to make decisions about the health care of people. They are based on the expertise of the individual practitioner integrated with the best clinical evidence from systematic review of credible research studies. Practice guidelines may take the form of algorithms, which are step-by-step methods for solving a problem, written directives, or a combination thereof.

**IN SUMMARY**

**Epidemiology** refers to the study of disease in populations. It looks for patterns such as age, race, and dietary habits of people who are affected with a particular disorder. These patterns are used to determine under what circumstances the particular disorder will occur. *Incidence* is the number of new cases arising in a given population during a specified time. *Prevalence* is the number of people in a population

Children are not miniature adults. Physical and psychological maturation and development strongly influence the type of illnesses children experience and their responses to these illnesses. Although many signs and symptoms are the same in persons of all ages, some diseases and complications are more likely to occur in the child. This chapter provides an overview of the developmental stages of childhood and the related health care needs of children. Specific diseases are presented in the different chapters throughout the book.

In the late 19th century, the infant mortality rate was 200 deaths per 1000 live births. Infectious diseases were rampant, and children, with their immature and inexperienced immune systems and their frequent exposure to other infected children, were especially vulnerable. To date, infant mortality rates in the United States have decreased significantly as the result of several factors, including

- Introduction of antimicrobial agents
- Infectious disease control
- Nutritional and technologic advances
- Collaborative prevention initiatives sponsored by federal and state programs, local health departments, the private sector, and the community

However, the US record low of 6.4 infant deaths per 1000 live births in 2009 was higher than that of many other industrialized countries in the world. Also of concern is the difference in mortality rates for white and nonwhite infants. Non-Hispanic black and American Indian/Alaska Native infants have consistently had a higher mortality rate than those of other racial or ethnic groups. The greatest disparity exists for non-Hispanic black infants. In 2006, the infant death rate for non-Hispanic black infants averaged 13.4 per 1000 live births in contrast to non-Hispanic white infants whose death rate averaged 5.6 per 1000.

One of the more perplexing causes of infant mortality is the incidence of preterm birth and low birth weight (LBW) infants among women of all races and classes. Reasons for the disparities and incidence of preterm and LBW newborns are related to the lack of prenatal care among non-Hispanic
black women and due to the number of twin, triplet, and higher-order multiple births among white women.2,5

### GROWTH AND DEVELOPMENT

After completing this section of the chapter, you should be able to meet the following objectives:

- Characterize the use of percentiles to describe growth and development during infancy and childhood.
- Describe the major events that occur during prenatal development from fertilization to birth.
- Define the terms low birth weight, small for gestational age, and large for gestational age.

The terms *growth* and *development* describe an ongoing dynamic process that begins with a fertilized ovum and continues throughout the infant, childhood, and adolescent periods until adulthood is achieved. *Growth* describes physical changes in body size as a whole or in its individual parts. *Development*, on the other hand, embraces other aspects of growth, such as changes in capabilities, acquisitions of skills, and psychosocial behaviors. Skill acquisition occurs in a standard fashion—from simple to complex and from general to the specific. In addition, pediatric development progresses in a predictable sequence—from head to toe (cephalocaudal) and from midline to the periphery (proximodistal) (Fig. 2.1). Each phase of development builds upon previous successes in order to achieve a higher-level skill. For example, the infant must first learn to roll over before he or she is able to sit up. Likewise, the toddler must learn to stand before he or she can walk.

Growth and development encompass a complex interaction between genetic and environmental influences, such as nutrition and sensory stimulation. The experience of each child is unique, and the patterns of growth and development may be profoundly different for individual children within the context of what is considered normal. Because of the wide variability, these norms often can be expressed only in statistical terms.

Evaluation of growth and development requires comparison of a child’s growth and development with a standard. Statistics are calculations derived from measurements that are used to describe the sample measured or to make predictions about the rest of the population represented by the sample. Because all children grow and develop at different rates, the standard must somehow take this individual variation into account. The standard typically is derived from measurements made on a sample of children deemed representative of the total population. When multiple measurements of biologic variables such as height, weight, head circumference, and blood pressure are made, most values fall around the center or middle of the values. Plotting the data on a graph yields a bell-shaped curve, which depicts the normal distribution of these continuously variable values. The mean and standard deviation are common statistics used in describing the characteristics of a population. The mean represents the average of the measurements. It is the sum of the values divided by the number of values. A normal bell-shaped curve is symmetric, with the mean falling in the center of the curve and one half of the values falling on either side of the mean. The standard deviation determines how far a value varies or deviates from the mean. The points one standard deviation above and below the mean include 68% of all values, two standard deviations 95% of all values, and three standard deviations 99.7% of all values.7 If a child’s height is within one standard deviation of the mean, he or she is as tall as 68% of children in the population. If a child’s height is greater than three standard deviations above the mean, he or she is taller than 99.7% of children in the population.

The bell-shaped curve can also be marked by percentiles, which are useful for comparison of an individual’s values with other values. When quantitative data are arranged in ascending and descending order, a middle value called the *median* can be described, with one half (50%) of the values falling on either side. The values can be further divided into percentiles. A percentile is a number that indicates the percentage of values for the population that are equal to or below the number. Percentiles are used most often to compare an individual’s
value with a set of norms. They are used extensively to develop and interpret physical growth charts and measurements of ability and intelligence.

Utilizing standardized growth charts can provide health professionals with a means to measure what is a normal growth trajectory of children or alert them to what is an atypical pattern. Currently, the United States uses two different growth charts based on the child’s age. The Centers for Disease Control and Prevention (CDC) recommends that the World Health Organization (WHO) (2006) growth chart be used to measure children ages 0 to 2 years and the 2000 CDC growth chart be utilized for all children older than 2. The WHO (2006) charts differ from previously used CDC growth charts in that the WHO charts were developed as the outcome of a rigorous longitudinal study, in which an international sample of children from diverse ethnic groups was sampled. Because the WHO charts were developed based on a global sample of children, they can be applied to children regardless of ethnicity, socioeconomic status, and type of feeding. Findings from recent studies support that the WHO growth charts provide a more sensitive indicator, which allows for earlier intervention in the very young age groups.

Because the WHO charts were developed based on a global sample of children, they can be applied to children regardless of ethnicity, socioeconomic status, and type of feeding. Findings from recent studies support that the WHO growth charts provide a more sensitive indicator, which allows for earlier intervention in the very young age groups. Growth charts for children can be accessed via the CDC Web site: http://www.cdc.gov/growthcharts/data_tables.htm.

**Prenatal Growth and Development**

Human development is considered to begin with fertilization, the union of sperm and ovum resulting in a zygote (Fig. 2.2). The process begins with the intermingling of a haploid number of paternal (23, X or Y) and maternal (23, X) chromosomes in the ampulla of the oviduct that fuse to form a zygote. Within 24 hours, the unicellular organism becomes a two-cell organism and, within 72 hours, a 16-cell organism called a morula. This series of mitotic divisions is called cleavage. During cleavage, the rapidly developing cell mass travels down the oviduct to the uterus by a series of peristaltic movements. Shortly after entering the uterus (about 4 days after fertilization), the morula is separated into two parts by fluid from the uterus. The outer layer gives rise to the placenta (trophoblast), and the inner layer gives rise to the embryo (embryoblast). The structure is now called a blastocyst. By the 6th day, the blastocyst attaches to the endometrium. This is the beginning of implantation, and it is completed during the 2nd week of development.

Prenatal development is divided into two main periods. The first, or embryonic, period begins during the 2nd week and continues through the 8th week after fertilization. During the embryonic period, the main organ systems are developed, and many function at a minimal level. The second, or fetal period, begins during the 9th week. During the fetal period, the growth and differentiation of the body and organ systems occur.

**Embryonic Development**

Embryonic development progresses through three stages. During the first stage, growth occurs through an increase in cell numbers and the elaboration of cell products. The second stage is one of morphogenesis (development of form), which includes massive cell movement. During this stage, the movement of cells allows them to interact with each other in the formation of tissues and organs. The third stage is the stage of differentiation or maturation of physiologic processes. Completion of differentiation results in organs that are capable of performing specialized functions.

Embryonic development begins during the 2nd week of gestation with implantation of the blastocyst. As implantation of the blastocyst progresses, a small space appears in the embryoblast, which is the primordium of the amniotic cavity. Concurrently, morphologic changes occur in the embryoblast that result in formation of a flat, almost circular bilaminar plate of cells called the embryonic disk. The embryonic disk, which forms the embryo proper, gives rise to all three germ layers of the embryo (i.e., ectoderm, mesoderm, endoderm). The 3rd week is a period of rapid development, noted for the conversion of the bilaminar embryonic disk into a trilaminar embryonic disk through a process called gastrulation. The ectoderm differentiates into the epidermis and nervous system, and the endoderm gives rise to the epithelial linings of the respiratory passages, digestive tract, and glandular cells of organs such as the liver and pancreas. The mesoderm becomes smooth muscle tissue, connective tissue, blood vessels, blood cells, bone marrow, skeletal tissue, striated muscle tissue, and reproductive and excretory organs.

The notochord, which is the primitive axis about which the axial skeleton forms, is also formed during the 3rd week. The neurologic system begins its development during this period. Neurulation, a process that involves formation of the neural plate, neural folds, and their closure, is completed by the 4th week. Disturbances during this period can result in brain and spinal defects such as spina bifida. The cardiovascular system is the first functional organ system to develop. The primitive heart, which beats and circulates blood, develops...
The fetal period extends from the 9th week to birth.16–18 Development during the fetal period is primarily concerned with rapid growth and differentiation of tissues, organs, and systems. Fetal weight gain is linear from 20 weeks’ gestation through 38 weeks’ gestation. In the last half of pregnancy, the fetus gains 85% of his or her birth weight. After 38 weeks’ gestation, the rate of growth declines, probably related to the constraint of uterine size and decreased placental function.16 After birth, weight gain resumes at a rate similar to intrauterine rates.

At birth, the average weight of the full-term newborn is 3000 to 4000 g. Infants weighing 2500 g or less at birth are classified as LBW. LBW is further broken down into very low birth weight (VLBW) and extremely low birth weight (ELBW). VLBW is defined as a birth weight less than 1500 g and ELBW as a birth weight less than 1000 g.19 An infant is considered term when born between the beginning of the 38th week and completion of the 41st week. An infant is considered premature when born before the end of the 37th week and postmature when born after the end of the 41st week. The lowest mortality rates occur among newborns with weights between 3000 and 4000 g and gestational ages of 38 to 42 weeks.20

Abnormal Intrauterine Growth

Growth of the fetus in the uterus depends on a multitude of intrinsic and extrinsic factors. Optimal fetal growth depends on efficient placental function, adequate provision of energy and growth substrates, appropriate hormonal environment, and adequate room in the uterus. Birth weight variability in a population is primarily determined by genetic factors, fetal sex, maternal health and nutrition, parity, intrinsic fetal growth potential, as well as other physiologic and environmental factors.21 Abnormal growth, which can occur at any time during fetal development, can have immediate and long-term consequences.

Lubchenco and Battaglia established standards for birth weight, gestational age, and intrauterine growth in the United States in the 1960s.22,23 With these standards, gestational age can be assessed and normal and abnormal growth can be identified. The Colorado Growth Curve places newborns into percentiles.22 The 10th through 90th percentiles of intrauterine growth encompass 80% of births.24 Growth is considered
Small for Gestational Age. Small for gestational age (SGA) is a term that denotes fetal undergrowth. SGA is defined as a birth weight less than 2 standard deviations below the mean for gestational age or below the 10th percentile. The terms small for gestational age and intrauterine growth retardation (IUGR) are used interchangeably, but are not synonymous. Impaired growth that occurs early in pregnancy during the hyperplastic phase of growth results in a symmetric growth retardation, and there is a proportionate decrease in length, weight, and head size for gestational age. This is irreversible postnatally. Causes of IUGR include chromosomal abnormalities, congenital infections, and exposure to environmental toxins. Impaired growth that occurs later in pregnancy during the hypertrophic phase of growth results in asymmetric growth retardation. Infants with IUGR due to intrauterine malnutrition often have weight reduction out of proportion to length or head circumference but are spared impairment of head and brain growth. Tissues and organs are small because of decreased cell size, not decreased cell numbers. Postnatally, the impairment may be partially corrected with good nutrition.

Gestational growth can be affected by maternal, placental, and fetal factors. The maternal environment can have a significant effect on birth weight and size. Underweight mothers are more likely to give birth to small-weight infants. Maternal nutrition and weight gain are influenced by many factors. Women at risk for poor nutrition and poor fetal growth include adolescents, women of low economic status, women with short interpregnancy intervals, women with unusual or stringent diet restrictions, and women who do heavy physical work during pregnancy. Various maternal diseases have been associated with restricted fetal growth, including prepregnancy hypertension, diabetes mellitus, and chronic maternal illnesses and infections. Growth retardation in the fetus may also be related to maternal exposure to environmental agents such as recreational drugs (drugs of abuse), therapeutic drugs, and environmental hazards. Tobacco in the form of cigarette smoking during pregnancy reduces birth weight. The reduction in birth weight is related to the number of cigarettes smoked.

Occupational exposure to agents such as industrial solvents used as thinners in paint, glue, and varnishes can pose a threat to the pregnant mother and fetus. Other factors that may decrease fetal growth include impairment of the uteroplacental and fetoplacental circulation. A broad range of pathologic processes can lead to a reduction in either uterine blood flow or circulation to the fetus; both conditions can result in IUGR.

Fetal factors associated with IUGR include numeric and structural chromosomal aberrations and gene abnormalities. Additionally, multiple births cause a progressive decrease in placental and fetal weight as the number of fetuses increases. Infants of twin and triplet gestations tend to weigh less than those of singlet gestations.

Mortality rates among infants with IUGR are 10 to 20 times greater than infants whose size and weight are appropriate for gestational age. The causes of this mortality are primarily due to hypoxia and congenital anomalies, although other complications include polycythemia, hyperbilirubinemia, and hypoglycemia. SGA infants have increased plasma volume and circulating red cell mass, which is most likely the result of fetal hypoxia and subsequent erythropoietin production. Many of the SGA infants also experience fasting hypoglycemia during the first days of life, probably as the result of depleted hepatic glycogen stores.

The long-term effects of growth retardation depend on the timing and severity of the insult. Many of these infants have developmental disabilities on follow-up examination, especially if the growth retardation is symmetric. If the insult occurred later because of placental insufficiency or uterine restraint, good nutrition may lead to catch-up growth allowing the infant to attain appropriate growth goals.

Large for Gestational Age. Large for gestational age (LGA) is a term that denotes fetal overgrowth and a birth weight above the 90th percentile. The excessive growth may result from maternal or fetal factors. Maternal factors include maternal obesity and diabetes. Fetal factors consist mainly of genetic and chromosomal abnormalities. Size of the biologic mother has been recognized as a factor that influences birth weight. Heavy women tend to have LGA infants. Women with diabetes also tend to have LGA infants, especially if the diabetes was poorly controlled during pregnancy.

Complications when an infant is LGA include birth asphyxia and trauma due to mechanical difficulties during the birth process, hypoglycemia, polycythemia, and hyperbilirubinemia. Maternal hyperglycemia exposes the fetus to increased levels of glucose, which stimulate fetal pancreatic islet hyperplasia and increased insulin secretion. Insulin increases fat deposition and the result is a macromesic (large body size) infant. Infants with macrosomia have enlarged viscera and are large and plump because of an increase in body fat. Fetal hyperinsulinemia is associated with fetal hypoxia and erythropoietin-induced polycythemia. The presence of polycythemia places the infant at risk for hyperbilirubinemia. LGA infants and infants of diabetic mothers (IDMs) are also at risk for hypoglycemia (to be discussed). Other potential long-term effects of LGA include insulin resistance, metabolic syndrome, overweight or obesity, diabetes, and early cardiovascular disease. In addition, there is increasing evidence that links high birth weight with overall leukemia risk.
Assessing Gestational Age

Gestational age assessment can be divided into two categories: prenatal assessment and postnatal assessment. Prenatal assessment of gestational age most commonly includes careful menstrual history, physical milestones during pregnancy (e.g., uterine size, detection of fetal heart rate, and movements), and prenatal tests for maturity (e.g., ultrasonography, amniotic fluid studies). The Nägele rule uses the first day of the LMP to calculate the day of labor by adding 7 days to the LMP and counting back 3 months. This method may be inaccurate if the mother is not a good historian or has a history of irregular menstrual cycles, which interferes with identification of a normal cycle.

Postnatal assessment of gestational age is done by examination of external physical and neuromuscular characteristics alone or in combination. Assessment of gestational age should be a part of every initial newborn examination. Accurate assessment of gestational age facilitates risk assessment and identification of abnormalities and allows for earlier interventions. Dubowitz and Ballard developed the most common methods used in nurseries today. The Dubowitz method is comprehensive and includes 21 criteria using external physical (11) and neuromuscular (10) signs. The estimate of gestational age is best done within 12 hours of birth and is accurate within 1 week of gestational age. The method is less accurate for infants born at less than 30 weeks gestational age. The Ballard method is an abbreviated Dubowitz method that includes 12 criteria, using 6 external physical and 6 neuromuscular signs. The New Ballard Score (NBS) was updated and modified to include newborns at gestational ages of 20 to 44 weeks and is the most commonly used method.

IN SUMMARY

Growth and development begin with union of ovum and sperm and are ongoing throughout a child’s life to adulthood. Abnormalities during this process can have profound effects on the individual. Prenatal development is composed of two periods, the embryonic period and the fetal period. During these periods, the zygote becomes the newborn with the organ maturity to make the adjustments necessary for extrauterine life. An infant is considered term when born between the beginning of the 38th week and completion of the 41st week. An infant is considered premature when born before the end of the 37th week and postmature when born after the end of the 41st week.

At birth, the average weight of the full-term newborn is 3000 to 4000 g. Infants weighing 2500 g or less at birth are classified as being LBW. LBW is further broken down into VLBW (<1500 g) and ELBW (<1000 g). Infants with a birth weight above the 90th percentile are considered LGA. The lowest mortality rates occur among newborns with weights between 3000 and 4000 g and gestational ages of 38 to 42 weeks.

INFANCY

After completing this section of the chapter, you should be able to meet the following objectives:

- Describe physical growth and organ development during the first year of life.
- Describe the causes and manifestations of neonatal hypoglycemia.
- Explain how the common health care needs of the premature infant differ from the health care needs of the term newborn or infant.

Infancy is defined as the time from birth to approximately 12 months of age. The first 4 weeks of an infant’s life is specifically referred to as the newborn or neonatal period. Infancy is a period of rapid physical growth and maturation. The infant begins life as a relatively helpless organism and through a process of progressive development, gains the skills to interact and cope with the environment. The infant begins life with a number of primitive reflexes and little body control. By 12 months, a child is able to stand alone, hold a cup and spoon, say several words, and play with toys.

Growth and Development

Length and Head and Chest Circumference

The average length of a full-term female neonate is 53 cm, and the average length of a mature male neonate is 54 cm. Length increases approximately 50% by the end of the first year. Much of this lengthening is primarily due to trunk growth. Typically, infants double their birth weight by 6 months and triple their birth weight by age 1.

The skull bones of newborn infants are incomplete and are connected by bands of connective tissue called sutures. At the junction of the sutures are wider spaces of unossified membranous tissue called fontanels. The larger anterior fontanel is palpable until about 18 months to 2 years of age, in comparison to the smaller posterior fontanel, which closes by 2 to 5 months of age. The softness of the cranial bones and loose connections of the sutures and fontanels enable the shape of the infant’s head to change (mold) during the birth process. The fibrous sutures of the infant’s skull also permit the cranium to enlarge during infancy and childhood. The increase in head size is greatest during the first 2 years, the period of most rapid brain development. Premature closure of any suture in the skull is called craniosynostosis. The cause of primary craniosynostosis is unknown, but genetic factors appear to be important. These malformations vary between genders depending on which suture is involved and are often associated with other skeletal abnormalities. The closed suture prevents growth from occurring in the affected area, but growth continues in the
equal in circumference. After 1 year, chest circumference exceeds head circumference. After birth, variations in growth and development are responsible for the differences in body proportions. For example, during the fetal period, the head is the predominant part because of the rapidly growing brain, whereas during infancy the trunk predominates, and in childhood the legs predominate.

**Organ Systems**

Organ systems must continue to grow and mature after delivery. Many are at a minimal level of functioning at birth. This often places the infant at risk for health problems.

**Respiratory System**. The child’s respiratory system is anatomically and physiologically different in comparison to the adult’s (Fig. 2.4). Differences primarily are due to smaller airway structures and a functionally immature system. Therefore, there is much less reserve capacity for this population. Beginning with the first breath, the respiratory system must make the transition from an intrauterine to an extrauterine existence in order to survive. The first breaths expand the alveoli and initiate gas exchange. The infant’s respiratory rate initially is rapid and primarily abdominal, but with maturation, respiratory rate gradually slows. Maturation of the respiratory system includes an increase in the number of alveoli and growth of the airways. Infants are obligatory nose breathers for the first 4 to 6 weeks of life. Therefore, any upper airway obstruction may cause respiratory distress. The trachea is small and close to the bronchi, and the bronchi’s branching structures enable infectious agents to be easily transmitted throughout the lungs. The softness of the supporting cartilage in the trachea, along with its small diameter, places the infant at risk for airway obstruction. The auditory (eustachian) tube is short and straight and closely communicates with the ear, putting the infant at risk for middle ear infections.

**FIGURE 2.3** • Craniosynostosis. (A) Scaphocephaly due to closure of the sagittal suture, in which the anterior fontanel is small or absent, results in a long, narrow, wedge-shaped cranium. (B) Oxycephaly due to premature closure of the coronal suture results in a high, tower-like cranium. (Adapted from Moore K. L., Dalley A. F. (2006). Clinically oriented anatomy (5th ed., p. 905). Philadelphia, PA: Lippincott Williams & Wilkins.)

unaffected sutures, resulting in an abnormally shaped head. The clinical consequences of premature suture closure depend on which suture is affected (Fig. 2.3).

Chest circumference at birth is slightly smaller than head circumference. By 1 year, the head and chest are approximately

Infants up to 4-6 weeks are obligate nose breathers

The tongue is larger in proportion to the mouth, making airway obstruction more likely in unconscious child

Smaller lung capacity and underdeveloped intercostal muscles give children less pulmonary reserve

Higher respiratory rates and demand for O₂ in young child make hypoxia easy to occur

Airway is smallest at the cricoid in children younger than 8 years

Smaller, narrower airway; make children more susceptible to airway obstruction and respiratory distress

Infants and toddlers appear barrel-chested

Children rely heavily on the diaphragm for breathing

Lack of firm bony structure to ribs/chest makes child more prone to retractions when in respiratory distress

Cardiovascular System. Birth initiates major changes in the cardiovascular system. Fetal circulation ends as the umbilical cord is clamped and the neonate begins to breathe. At birth, three fetal shunts (foramen ovale, ductus venosus, and ductus arteriosus) undergo a functional closure due to the directional change in blood flow (Fig. 2.5). Full anatomic closure of the three shunts may take weeks to months for the healthy term newborn and may take longer in preterm neonates. At birth, the size of the heart is large in relation to the chest cavity. The size and weight of the heart double the first year. Initially, the right ventricle is more muscular than the left ventricle, but this reverses as the left ventricle becomes the primary structure to push blood out into systemic circulation. As the infant grows, the heart rate gradually slows, and systolic blood pressure rises.

Thermoregulation. Maintaining a stable body temperature is a function of heat production and conservation coupled with heat loss. Heat production in response to cold stress for an adult can occur through peripheral vascular constriction, inhibition of sweat, voluntary muscle activity, involuntary muscle activity (shivering), and nonshivering thermogenesis. However, many of these responses occur rarely in the neonate. The main source of heat production is through nonshivering thermogenesis. Brown fat is found in full-term newborns. Thus, thermal regulation is a greater challenge for preterm and LBW infants.

Neonates lose heat to the environment through the following mechanisms:
- Radiation, transfer of heat from a warmer to cooler area that is not in contact with the body
- Convection, transfer of heat to the surrounding environment, influenced by air currents
functioning until approximately 3 months of age. The newborn’s first stool is called meconium. It is dark black-green in color and is composed of amniotic fluid, intestinal secretions, shed mucosal cells, and sometimes blood from ingested maternal blood or minor bleeding of intestinal tract vessels. Passage of meconium should occur within the first 24 to 48 hours in healthy term newborns, but may be delayed for up to 7 days in preterm newborns or in newborns who do not receive enteral nutrition because of illness. If a meconium stool is not passed within the recommended time frame after delivery, then a congenital anomaly may be suspected.

At birth, sucking may be poor and require several days to become effective. The tongue thrust reflex is present and aids in sucking, but it disappears at approximately 6 months of age. Stomach capacity for the newborn holds approximately 60 to 90 mL, but because of the limited capacity and rapid emptying, infants require frequent feeding.

**Genitourinary System.** The infant’s genitourinary system is immature, and most digestive processes are poorly functioning until approximately 3 months of age. The newborn’s first stool is called meconium. It is dark black-green in color and is composed of amniotic fluid, intestinal secretions, shed mucosal cells, and sometimes blood from ingested maternal blood or minor bleeding of intestinal tract vessels. Passage of meconium should occur within the first 24 to 48 hours in healthy term newborns, but may be delayed for up to 7 days in preterm newborns or in newborns who do not receive enteral nutrition because of illness. If a meconium stool is not passed within the recommended time frame after delivery, then a congenital anomaly may be suspected.

At birth, sucking may be poor and require several days to become effective. The tongue thrust reflex is present and aids in sucking, but it disappears at approximately 6 months of age. Stomach capacity for the newborn holds approximately 60 to 90 mL, but because of the limited capacity and rapid emptying, infants require frequent feeding.

**Heat loss in the newborn.**
- Conduction, transfer of heat to a cooler surface that is in direct contact with the body
- Evaporation, cooling secondary to water loss from the skin27,30 (Fig. 2.6)

Heat loss in the preterm infant is accelerated because of the higher ratio of surface area to body mass, reduced insulation of subcutaneous tissue, and water loss through immature skin.

The thermal environment of the preterm infant must be regulated carefully. Ideally, the infant should be kept in a neutral environment to maintain a stable core body temperature with minimal need for metabolic heat production through oxygen consumption. The neutral thermal environment for a given infant depends on size, gestational age, and postnatal age. Interventions to prevent heat loss and maintain a thermal environment include:

- Drying and wrapping newborns
- Placing in warmed cribs or radiant warmers
- Maintaining neutral room temperature
- Lying the naked newborn against a parent’s skin (skin-to-skin care) so that heat is transferred from the parent to the newborn27,32,34

**Gastrointestinal System.** The infant’s gastrointestinal system is immature, and most digestive processes are poorly functioning until approximately 3 months of age. The newborn’s first stool is called meconium. It is dark black-green in color and is composed of amniotic fluid, intestinal secretions, shed mucosal cells, and sometimes blood from ingested maternal blood or minor bleeding of intestinal tract vessels. Passage of meconium should occur within the first 24 to 48 hours in healthy term newborns, but may be delayed for up to 7 days in preterm newborns or in newborns who do not receive enteral nutrition because of illness. If a meconium stool is not passed within the recommended time frame after delivery, then a congenital anomaly may be suspected.

At birth, sucking may be poor and require several days to become effective. The tongue thrust reflex is present and aids in sucking, but it disappears at approximately 6 months of age. Stomach capacity for the newborn holds approximately 60 to 90 mL, but because of the limited capacity and rapid emptying, infants require frequent feeding.

**Genitourinary System.** The infant’s genitourinary system is functionally immature at birth. The kidneys do not concentrate urine well until approximately 6 weeks of age. The first void should occur within 24 hours of birth and is typically small in amount; the urine is light in color and odorless. Small bladder capacity causes frequent voiding. Totally daily volume of urine output increases during the first week, from

**FIGURE 2.6 • Heat loss in the newborn.**
30 to 300 mL. Newborns who do not void or who experience a projectile stream of urine may need further evaluation for suspected congenital anomalies or obstructions within the urinary system.27

**Nervous System.** The nervous system undergoes rapid maturation and growth during infancy. In contrast to other systems that grow rapidly after birth, the nervous system grows proportionately more rapidly in utero. The most rapid period of fetal brain growth is between 15 and 20 weeks, gestation, at which time there is a significant increase in neurons. A second increase occurs between 30 weeks’ gestation and 1 year of age. Around 12 months, the weight of the infant brain is two times heavier than it was at birth and is about 2/3 that of the adult size.6

At birth, the nervous system is incompletely integrated, but sufficiently developed to sustain extrauterine life. Most of the neurologic reflexes are primitive reflexes. Normal newborn reflexes can be used to evaluate the newborn and infant’s developing CNS; several of these reflexes include palmar (grasp), Moro (startle), rooting (sucking), and stepping (placing) reflexes.

The maturation of the nervous system includes an increase in the size of neurons, size and number of glial cells, and number of interneuron connections and branching of axons and dendrites. As this maturation progresses, the level of infant functioning increases from simple to complex and from primitive reflexes to purposeful movement. Cortical control of motor functions is closely associated with myelination of nerve fibers. Myelination of the various nerve tracts progresses rapidly after birth and is a necessary process to allow for coordinated movements and decision making, along with higher-order cognitive, behavioral, and emotional functions.35

Beginning in the cerebellum, pons, and internal capsule, myelination progresses to posterior end of the corpus callosum (between 3 and 4 months), to the occipital and parietal lobes (between 4 and 6 months), and then to anterior end of the corpus callosum, the frontal and the temporal lobes of the brain (between 6 and 8 months).19 Acquisition of fine and gross motor skills depends on this myelination and maturation. Connective pathways between neurons continue to form into toddlerhood, but only 50% of the total synapses are utilized as adults.27 Thus, it has been suggested that the human brain and neuronal network adapt to the specific environment at hand by refining and strengthening only the networks that are necessary for function.27 The first year of life also is filled with psychosocial developmental milestones for the infant. Basic needs must be met before the infant can accomplish these developmental tasks. Erikson described the development of a sense of trust as the task of the first stage.36 If trust is not acquired, the infant becomes mistrustful of others and frustrated with his or her inability to control the surrounding environment.

**KEY POINTS**

**INFANCY**

- Infancy, which is the time from birth to 12 months of age, is a period of rapid physical and developmental growth and maturation.
- Physiologic changes at birth and immature organ systems place the neonate and infant at risk for a variety of health problems.

**Health Problems of the Neonate**

The most profound physiologic changes required of the newborn occur at the time of transition from intrauterine to extrauterine life. Onset of respiration must begin at birth for survival. The fetal shunts (i.e., foramen ovale and ductus arteriosus) begin to close, and the circulation of blood changes from a serial to parallel circuitry. Heat regulation is a response critical to the infant’s survival. The newborn’s large surface area and lack of subcutaneous fat predispose to excessive heat loss. Blood glucose concentration in the fetus is approximately 15 mg/dL less than maternal glucose concentrations and can drop to hypoglycemic levels in certain high-risk groups.

**Distress at Birth and the Apgar Score**

The Apgar score, devised by Dr. Virginia Apgar, is a scoring system that evaluates infant well-being at birth.37 The system addresses five categories (i.e., heart rate, respiratory effort, muscle tone, reflex irritability, and color) with a total score ranging from 0 to 10, depending on the degree to which these functions are present (Table 2.1). Evaluations are performed at 1 minute and 5 minutes after delivery. A score of 0 to 3 is

indicative of severe distress, 4 to 6 of moderate distress, and 7 to 10 of mild to no distress. Most infants score 6 to 7 at 1 minute and 8 to 9 at 5 minutes. If the score is 7 or less, the evaluation should be repeated every 5 minutes until a score of 7 or greater is obtained. An abnormal score at 5 minutes is more predictive of problems with survival and neurologic outcome than at 1 minute.20,27

Neonatal Hypoglycemia
Glucose concentration normally decreases in the immediate postnatal period, but the level typically stabilizes to a value of 50 mg/dL or higher within the first 3 hours of life, for normal term infants.38 If concentrations remain below 45 mg/dL, then the blood level should be considered abnormal and indicative of hypoglycemia.27 In neonates, classic symptoms of hypoglycemia are not always present when there is a low blood glucose level; the lack of symptoms can be misleading and may jeopardize brain metabolism.38 Furthermore, if the neonate were to experience hypoxemia or ischemia, in addition to hypoglycemia, then the newborn is at risk for permanent brain damage.38 Thus, all infants should be screened for hypoglycemia. Blood glucose can be easily measured by heel stick using a glucometer. Signs and symptoms of neonatal hypoglycemia include cyanosis, apnea, hypothermia, hypotonia, poor feeding, lethargy, and seizures.38 Newborns who are at particular risk for neonatal hypoglycemia are IDMs and premature and SGA newborns.

The factors related to hypoglycemia in IDMs are hyperinsulinemia and diminished glucagon secretion.38 Glucose readily crosses the placenta and consequently IDMs are exposed to elevated blood glucose levels, a condition that stimulates islet cell hypertrophy and hyperplasia in the neonate. Several other physiologic processes occur during the transition to extrauterine life for IDMs. The combined physiologic changes result in an abnormal plasma hormonal pattern of high insulin, low glucagon, and low epinephrine; the hormonal changes inhibit the neonate’s endogenous glucose production, causing a state of hypoglycemia.38 Newborns with high insulin blood levels or hyperinsulinemia are often LGA; however, if the diabetes was well controlled during the mother’s pregnancy, labor, and delivery, then the newborn may be near normal size and may be less likely to have hypoglycemia.38 Premature and SGA infants are two other at risk population for developing hypoglycemia. Factors related to hypoglycemia for these infants include inadequate liver glycogen stores, muscle protein, and body fat, which is needed to meet energy needs.38 Because these infants are small for size, their enzyme systems for gluconeogenesis may not have developed fully.38 In addition, infants with perinatal asphyxia and some SGA newborns may have transient hyperinsulinemia, which promotes hypoglycemia.38

Neonatal Jaundice/Hyperbilirubinemia
Hyperbilirubinemia in neonates pertains to an elevated serum level of bilirubin. With this condition, the infant’s skin appears yellow or jaundice in color due to the excessive accumulation of unconjugated, lipid-soluble bilirubin.39,40 During pregnancy, the fetus’s circulating bilirubin was eliminated through the mother’s liver via the placenta. However, after birth, the neonate’s immature biliary system takes over. This transitional process takes time and more than 50% of all full-term and most preterm infants develop hyperbilirubinemia. Bilirubin occurs as a by-product from the breakdown of hemoglobin in red blood cells. In newborns, red blood cells live for a shorter length of time, 70 to 90 days, in contrast to older children, in whom red blood cells live for 120 days.39 Normally, about two thirds of the unconjugated bilirubin produced by a term newborn can be effectively cleared by the liver. However, the relative immaturity of the newborn liver and the shortened life span of the fetal red blood cells may predispose the term newborn to hyperbilirubinemia. With the establishment of sufficient enteral nutrition, regular bowel elimination, and normal fluid volume, the liver is usually able to clear the excess bilirubin.

There are several types of neonatal jaundice: physiologic, kernicterus, and breast milk jaundice. Physiologic jaundice is the term used to describe the condition that occurs in the immediate neonatal period without signs of illness. The average level of unconjugated or indirect-reacting bilirubin in umbilical cord blood is 1 to 3 mg/dL.40 Jaundice is noted in the full-term infant 2 to 3 days after birth. The elevated serum bilirubin level peaks at 5 to 6 mg/dL between the 2nd and 4th day of life and decreases to below 2 mg/dL between 5 and 7 days of life.40

Jaundice and its underlying hyperbilirubinemia are considered pathologic if their time of appearance, duration, and pattern of appearance vary significantly from those of physiologic jaundice.40 The development of kernicterus or bilirubin encephalopathy is a neurologic syndrome resulting from extremely high levels of serum bilirubin (>25 to 30 mg/dL), in which bilirubin crosses the blood–brain barrier and deposits its unconjugated bilirubin in the basal ganglia and brain stem nuclei.39,40 Kernicterus develops at lower bilirubin levels in preterm infants. The exact level at which bilirubin levels are harmful to infants with LBW is unclear.

Although uncommon, jaundice and elevated unconjugated bilirubin levels can also occur in breast-fed infants (breast milk jaundice). It occurs after the 7th day of life, with maximal concentrations as high as 10 to 12 mg/dL reached during the 2nd to 3rd week.40 Cessation of breast-feeding for 1 to 2 days is recommended, and substitution of formula usually results in a rapid decline in serum bilirubin, after which breast-feeding can usually be resumed without return of hyperbilirubinemia.

The goal of therapy for neonatal jaundice and hyperbilirubinemia is to prevent the concentration of bilirubin in the blood from reaching neurotoxic levels.39,40 Therapeutic interventions include frequent breast-feeding to prevent dehydration, phototherapy using overhead or fiber-optic pads, and in severe cases, exchange blood transfusions.39 Phototherapy uses a special artificial blue light to alter bilirubin so it may be more readily excreted in the urine and stool. The need for
exchange transfusions is infrequent, but is indicated when bilirubin levels reach 25 to 30 mg/dL or if anemia is present as a result of the hemolytic process.39

**Birth Injuries**

Injuries sustained during the birth process are responsible for less than 2% of neonatal mortality and morbidity.40 Predisposing factors for birth injuries include (1) maternal age, less than 16 or greater than 35; (2) primigravida; (3) cephalopelvic disproportion; (4) prolonged or rapid labor; (5) deep transverse arrest of descent of presenting part of the fetus oligohydramnios; (6) abnormal presentation; (7) use of midcavity forceps or vacuum extraction; (8) VLBW infant; (9) extreme prematurity; (10) large fetal head (e.g., hydrocephalus); (11) fetal anomalies; and (12) fetal weight41 (p. 64).

**Cranial Injuries.** The contour of the head of the newborn often reflects the effects of the delivery presentation. The softness of the cranial bones in infants and their loose connections at the sutures and fontanels allow the shape of head to mold during birth. In a vertex (headfirst) delivery, the head is usually flattened at the forehead with the apex rising and forming a plane at the end of the parietal bones and the posterior skull or occiput dropping abruptly (Fig. 2.7). By 1 to 2 days of age, the head has taken on a more oval shape.27 Such molding does not occur in infants born by breech presentation or cesarean section.

_Caput succedaneum_ is a localized area of scalp edema caused by sustained pressure of the presenting part against the cervix, during a vertex delivery.42,43 The caput succedaneum may extend across suture lines and have overlying petechiae, purpura, or ecchymosis. No treatment is needed, and it usually resolves over the first week of life. _Cephalhematoma_ is a subperiosteal collection of blood from ruptured blood vessels.42,43 The margins are sharply delineated and do not cross suture lines. It usually is unilateral, but it may be bilateral, and it usually occurs over the parietal area. The subperiosteal bleeding may be slow and therefore not apparent for 24 to 48 hours. The overlying skin is not discolored. Skull fractures may be present. Usually the fractures are linear, are nondepressed, and do not require treatment. Infants with cephalhematomas are usually asymptomatic. Management includes monitoring for hyperbilirubinemia. Resolution usually occurs over a period of 2 weeks to 3 months. Rarely, a cephalhematoma may develop complications. Large cephalhematomas may result in significant blood loss, causing anemia and hyperbilirubinemia. In rare cases, an infant may develop a subdural or subarachnoid hemorrhage. Calcium deposits occasionally develop, and the swelling may remain for the first year.

**Fractures.** Skull fractures are uncommon because the infant’s compressible skull is able to mold to fit the contours of the birth canal. However, fractures can occur and more often follow a forceps delivery or severe contraction of the pelvis associated with prolonged, difficult labor. Skull fractures may be linear or depressed. Uncomplicated linear fractures often are asymptomatic and do not require treatment. Depressed skull fractures are observable by the palpable indentation of the infant’s head. They require surgical intervention if there is compression of underlying brain tissue. A simple linear fracture usually heals within several months.41–43

The clavicle is the most frequently fractured bone during the birth process.44,45 It occurs when delivery of the shoulders is difficult in vertex (i.e., headfirst) or breech presentations. The infant may or may not demonstrate restricted motion of the upper extremities, but passive motion elicits pain. There may be discoloration or deformity and, on palpation, crepitus (i.e., a crackling sound from bones rubbing together), and irregularity may be found. Treatment of complete fractures consists of immobilizing the arm and shoulder and providing pain relief.44,45

**Peripheral Nerve Injuries.** The brachial plexuses are situated above the clavicles in the anterolateral bases of the neck. They are composed of the ventral rami of the fifth cervical (C5) through the first thoracic (T1) nerves. During vertex deliveries, excessive lateral traction of the head and neck away from the shoulders may cause a stretch injury to the brachial plexus on that side. In a breech presentation, excessive lateral traction on the trunk before delivery of the head may tear the lower roots of the cervical cord. If the breech presentation includes delivery with the arms overhead, an injury to the fifth and sixth cervical roots may result. When injury to the brachial plexus occurs, it causes paralysis of the upper extremity. The paralysis often is incomplete.43,45

Brachial plexus injuries include three types: Erb palsy (i.e., upper arm), Klumpke palsy (i.e., lower arm), and paralysis of the entire arm. Risk factors include an LGA infant and a

![FIGURE 2.7](image)
Mortality and morbidity are increased in the premature population, with their rates inversely proportional to the length of gestation. Although rates of preterm births in the US are on the decline overall (12.3% in 2008), there continues to be a national focus to further reduce the incidence of LBW and VLBW infants.46 The national goal is to reduce the number of LBW infants to be less than 5% of live births and VLBW infants to an incidence of less than 0.9% of live births from baselines of 7.6% and 1.4%, respectively.27 Aims for this national initiative are to improve prenatal care for all ethnicities and prevent preterm births and the associated medical complications that arise in premature infants as the result of increased susceptibilities and immature organ systems. The premature infant is poorly equipped to withstand the rigors of extraterine transition. The organ systems are immature and may not be able to sustain life. The respiratory system may not be able to support gas exchange; the skin may be thin, gelatinous, and easily damaged; the immune system is compromised and may not effectively fight infection; and the lack of subcutaneous fat puts the infant at risk for temperature instability. Complications of prematurity include respiratory distress syndrome (RDS), pulmonary hemorrhage, transient tachypnea, congenital pneumonia, pulmonary air leaks, bronchopulmonary dysplasia, recurrent apnea, glucose instability, hypocalcemia, hyperbilirubinemia, anemia, intraventricular hemorrhage (IVH), necrotizing enterocolitis (NEC), circulatory instability, hypothermia, bacterial or viral infection, retinopathy of prematurity, and disseminated intravascular coagulopathies.

### Respiratory Problems

The respiratory distress syndrome is the most common complication of prematurity. The primary cause of RDS is the lack of surfactant in the lungs. At 24 weeks’ gestation, there are small amounts of surfactant and few terminal air sacs (i.e., primitive alveoli), with underdeveloped pulmonary vascularity. If an infant is born at this time, there is little chance of survival. By 26 to 28 weeks, there usually is sufficient surfactant and lung development to permit survival. Surfactant deficiency leads to decreased lung compliance, reduced alveolar ventilation, and atelectasis. Clinical manifestations include grunting, rapid shallow respirations, retractions, nasal flaring, and cyanosis.

The availability of exogenous surfactant replacement therapy has greatly improved the outcome of RDS. The administration of corticosteroids to women in preterm labor has been shown to accelerate lung maturation in their infants. Antenatal steroids are now the standard of care for women in preterm labor up to 34 weeks. However, because the survival rate of the sickest infants has improved and because their management typically includes mechanical ventilation, the incidence of other complications has increased. These include air leak syndromes, bronchopulmonary dysplasia, and IVH.27,45

**Periodic breathing** and **apnea of prematurity** are other common respiratory problems in premature infants. Brief apneic pauses lasting 5 to 10 seconds (periodic breathing) is a common finding and most often resolves without any obvious cause. In contrast, **apnea of prematurity** is defined as failure to

---

**FIGURE 2.8** • Position of the right arm in an infant with Erb palsy. After partial upper arm paralysis, the upper arm is held in a “waiter’s tip” position with adduction and internal rotation of the shoulder, extension of the elbow with pronation of the forearm, and flexion of the wrist and fingers.
Intraventricular Hemorrhage. IVH or bleeding into the ventricles of the brain is a significant concern within the premature infant population (Fig. 2.9). Bleeding is thought to result from alterations in cerebral blood flow to damaged vessels in the germinal matrix, an early developmental structure that contains a fragile vascular bed that is poorly supported by connective tissue. The incidence of IVH increases with decreasing birth weight and gestational age. Incidence is greatest in those who weigh less than 1500 g and who are less than 28 weeks’ gestation. New-onset IVH is rare after the first month of life.

Risk factors for IVH include prematurity, RDS, hypotension, chorioamnionitis, preeclampsia, hypothermia, patent ductus arteriosus, and umbilical lines. Cranial ultrasonography is the method of choice for diagnosis of IVH. A standard grading system using cranial ultrasonography has been adopted for evaluation of IVH (Chart 2.1). Clinical manifestations are determined by the level (grade) of involvement. The most common symptoms are poor muscle tone, lethargy, apnea, decreased hematocrit, and somnolence. In some cases (grades I and II), infants may be asymptomatic. Most hemorrhages resolve, but the more severe hemorrhages may obstruct the flow of cerebrospinal fluid, causing a progressive hydrocephalus or other neurologic abnormalities.

Necrotizing Enterocolitis. NEC is an acquired life-threatening condition of the neonate’s gastrointestinal tract. The disorder is characterized by necrosis of the mucosal or submucosal layers of the intestine and accounts for 1% to 7% of admissions to the neonatal intensive care unit. Premature infants are at greatest risk for NEC due to the immaturity of the gastrointestinal tract. The disorder is rarely seen in term infants, and incidence and fatality increase with decreasing birth weight and gestational age.

Although the exact causes of NEC are unknown, it is suspected that three factors contribute to the disease: intestinal ischemia, effect of enteral feedings (metabolic substrate), and pathogenic organisms. NEC most likely develops from an interaction between loss of mucosal functioning caused by a variety of factors (i.e., intestinal ischemia, infection, inflammation) and the infant’s response to the injury (circulatory, immunologic, inflammatory). Any portion of the bowel may be affected, but the distal part of the ileum and proximal segment of the colon are involved most often. The necrosis of the intestine may be superficial, affecting only the mucosa or submucosa, or may extend through the entire intestinal wall (Fig. 2.10). If the full thickness of the intestinal wall is damaged, perforation can result. NEC usually has its onset in the 2nd week, but it may occur as late as the 3rd month in VLBW infants.

Clinical manifestations of NEC are variable. However, the classic initial symptoms are usually feeding intolerance, abdominal distention, and bloody stools shortly after the first

---

**Chart 2.1**

**Classification of Intraventricular Hemorrhage**

| Grade I: Germinal matrix hemorrhage only |
| Grade II: Germinal matrix hemorrhage with extension into the ventricles |
| Grade III: Germinal matrix hemorrhage with dilated ventricles |
| Grade IV: Intraventricular hemorrhage with extension into brain tissue |

Typically, sepsis occurs after the first week of life.45,52 Late-onset infection is commonly acquired during delivery or up to 7 days after birth.45

Additionaly, the majority of maternal antibodies (immunoglobulin [Ig] G) are transferred during the later weeks of gestation.45 Moreover, cord Ig levels are directly proportional to gestational age.45,49 Prevention strategies include promotion of breast-feeding, as there is a decreased incidence of NEC in infants who receive human milk, and administration of probiotic preparations to increase mucosal barrier function, enhance nutrition, and reduce mucosal colonization by potential pathogens.45–49

Neonatal Infection and Sepsis. Bacterial sepsis is characterized by signs of systemic infection in the presence of bacteria in the bloodstream. The incidence of bacterial sepsis in the newborn is about one to two newborns per every 1000 live births in the United States, and up to 20% of infants in neonatal intensive care units have positive blood cultures.52 Preterm infants have a higher risk of becoming infected than full-term infants (1:250 in preterm and 1:1500 in full term), because the majority of maternal antibodies (immunoglobulin [Ig] G) are transferred during the later weeks of gestation.45,49 Additionally, cord Ig levels are directly proportional to gestational age.45

The terms early onset and late onset are often used to describe two different categories related to the onset of infection. Early-onset infections are typically defined as those acquired during delivery or up to 7 days after birth. Late-onset sepsis typically occurs after the first week of life.45 In preterm infants, because of the high mortality and morbidity rates associated with NEC.45,49

Optimal prognosis depends on early diagnosis and implementation of appropriate therapy. Thus, frequent and careful assessment and evaluation of the infant’s physical condition can have a significant impact on outcome. Administration of antimicrobial agents to mothers during the intrapartum period or to newborns immediately postpartum has been shown to reduce the risk of early-onset GBS infection. The CDC in collaboration with the American College of Obstetricians and Gynecologists and the American Academy of Pediatrics developed guidelines for prevention of neonatal GBS disease in 1996.51 GBS disease continues to be a threat to the newborn because of the high mortality and morbidity rates associated with the disease.51

with the disease and the increased survival of smaller and more preterm newborns with a higher risk for GBS disease.

**Health Problems of the Infant**

In the United States, infant mortality rates have steadily declined during the past several decades. However, the top five leading causes of infant death are congenital malformations, disorders related to short gestation and LBW, sudden infant death syndrome (SIDS), newborn affected by maternal complications of pregnancy, and unintentional injuries.56 Of the unintentional injuries, suffocation was the primary cause of death for this age group.57 Infants are also prone to numerous health problems during this first year of life, which may become serious if not recognized and treated appropriately. Many of them may be precipitated by the relative immaturity of the organ systems. Factors that may affect an infant’s long-term health status include nutritional disturbances, feeding difficulties, irritable infant syndrome or colic, and failure to thrive (FTT). Additionally, childhood illnesses may be a problem if the infant is not adequately immunized. Therefore, injury and illness prevention is vital during infancy.

**Nutritional Disturbances**

Some infants may experience difficulties in consuming mother’s milk or infant formulas that are based on cow’s milk because of lactase deficiency. Lactase is an enzyme that breaks down lactose, the carbohydrate found in human milk and cow’s milk. Some infant formulas contain carbohydrates other than lactose. These formulas are made from soybeans. Other feeding intolerances also may occur. Treatment of any milk or formula intolerance depends on identification of the specific offender and elimination of it from the diet. Newborns and infants frequently exhibit “spitting up” or regurgitation of formula, despite the absence of a formula intolerance. In general, cow’s milk–based formulas are preferable to soy-based formulas, and changing to a soy-based formula should be undertaken only when there is a proven case of intolerance. It is important that all claims of formula intolerance be thoroughly investigated before an infant is changed to a soy-based formula. Education of the parents about the signs and symptoms of intolerance and reassurance that spitting up formula is normal may be all that is required. An infant that is gaining weight, appears alert and well nourished, has adequate stools, and demonstrates normal hunger is unlikely to have a formula intolerance.

**Irritable Infant Syndrome or Colic**

Colic is usually defined as paroxysmal abdominal pain or cramping in an infant and usually is manifested by inconsolable crying, drawing up of the legs to the abdomen, and extreme irritability.58 Episodes of colic may last from several minutes to several hours a day. During this time, most efforts to soothe the infant or relieve the distress are unsuccessful. Colic is a temporary problem that resolves for the majority (up to 90%) of infants by 3 to 4 months of age.59

“Colic has often been described by the rule of three—crying for more than 3 hours per day, for more than 3 days per week, for more than 3 weeks”54 (p. 45). When parents seek advice about a colicky baby, their concerns should be substantiated by their health care provider. Because there may be an underlying organic cause, a careful history and physical examination should be performed.

There is no single etiologic factor that causes colic. Some reasons for the crying are related to feeding problems including hunger, air swallowing, gastroesophageal reflux, and food intolerance. Therefore, the treatment of colic is not precise. Many nonmedical techniques and pharmacologic preparations have been tried. However, medications have not proven to be effective and should be avoided.58 Nonpharmacologic interventions include soothing voices or singing, swaddling, slow rhythmic rocking, walking, white noise, and gentle vibration, such as car rides.56 Support of the parents is probably the single most important factor in the treatment of colic. Many times the mother (or primary care provider) may be afraid to state just how frustrating it can be to be unable to console the infant. An open discussion of this frustration can help the mothers or care providers recognize that their feelings of frustration are normal; frequently, this gives them the added support needed to deal with their infant. Because the incidence of colic in breast-fed and bottle-fed infants is similar, mothers should be encouraged to continue breast-feeding so that the infant will continue to receive the many beneficial effects of breast-feeding.

**Failure to Thrive**

Failure to thrive is a term that refers to the failure to meet expected standards of growth for infants and young children due to the inability to obtain or use essential nutrients.60 FTT can be defined as growth below the 3rd or 5th percentile or a change in growth that has dropped two percentiles within a brief time span. FTT may be organic or nonorganic.61 Organic FTT is the result of a physiologic cause that prevents the infant from obtaining or using nutrients appropriately. An example of organic FTT is inadequate growth of an infant with deficient energy reserve because of a congenital defect that makes sucking and feeding difficult. Nonorganic FTT is the result of psychological factors that prevent adequate intake of nutrition, such as poverty or poor child–parent interaction.61

Diagnosis of the type of FTT depends on careful examination and history of the infant and serial follow-up evaluations. Cases of organic FTT usually are easier to diagnose than cases of nonorganic FTT. Diagnosis of nonorganic FTT requires extensive investigation of history, family situation, relationship of the care provider to the infant, and evaluation of feeding practices. A nonorganic basis should be considered early in every case of FTT in order to prevent potential developmental delays and social and emotional problems.61

Therapy for FTT depends on the cause. Because long-term nutritional deficiencies can result in impaired physical and intellectual growth, provision of optimal nutrition is essential. Methods to increase nutritional intake by adjusting
caloric density of the formula or by parenteral nutrition may be required in cases of organic FTT.

**Sudden Unexpected Infant Death/Sudden Infant Death Syndrome**

Sudden unexpected infant death (SUID) is defined as the unexpected death of an infant, which, after autopsy and investigation, may be attributed to metabolic disorders, hypothermia or hyperthermia, neglect or homicide, poisoning, or accidental suffocation.\(^6^2\) SIDS is similar in definition, except that the cause of death is inconclusive and remains unexplained after autopsy, investigation of the death scene, and review of the child’s medical and family history.\(^6^3,6^4\) SIDS is rare during the first month of life, increases to a peak between 2 and 4 months of life, and then declines.\(^6^3,6^4\) Although its incidence has decreased since the 1994, SIDS continues to account for more infant deaths beyond the neonatal period than any other cause.\(^6^4\) This campaign advocated that infants be laid down to sleep in the supine position.

Factors associated with an increased risk of SIDS include sleeping in the prone position, particularly on soft bedding; pre-maturity and LBW; overheating; African American or Native American race; and exposure to environmental cigarette smoke.\(^6^3,6^5\) Additionally, there are several maternal risk factors that increase the incidence of SIDS: young maternal age (less than 20), lack of or inadequate prenatal care, and smoking or substance use during pregnancy.\(^6^3,6^6\) Sleeping prone has consistently been shown to increase the risk of SIDS. The American Academy of Pediatrics now recommends that placing infants on their backs confers the lowest risk and is the preferred position.\(^6^4\) Soft sleep surfaces on beds, such as comforters and pillows, increase the risk of SIDS, as does bed sharing between infants and adults.

The exact cause of SIDS is unknown. Several theories have attempted to explain the incidence of SIDS, including

- Genetic factors
- Brain abnormalities (neurotransmitter abnormalities in brain stem), which prevent effective cardiorespiratory control
- Cardiac dysfunction (prolonged QT interval)
- Carbon dioxide rebreathing from sleeping prone in soft bedding\(^6^3,6^6\)

A diagnosis of SIDS can be made only if an autopsy is performed to exclude other causes of death. Differentiation of child abuse from SIDS is an important consideration, and each case of SIDS must be subjected to careful examination.

Support of family members of an infant who dies of SIDS is crucial. Parents frequently feel guilty or inadequate as parents. The fact that there must be close scrutiny to differentiate a SIDS death from a death by child abuse adds to the guilt and disappointment felt by the family. After a diagnosis of SIDS is made, it is important that the parents and other family members receive information about SIDS. Health care providers need to be fully aware of resources available to families with a SIDS death. The siblings of the child who died of SIDS also need information and support to assist with the grief process.\(^6^7\)

**Injuries**

Although the leading causes of death during the infant period are related to medical conditions, unintentional injuries do occur. In fact, accidents are the fifth leading cause of death during the infant period.\(^5^6,5^7\) Suffocation was ranked the highest cause of injury-related death for this age group.\(^5^7\) Accidents may not be the top cause of infant death, but they are a significant cause and prevention education is critical. As the infant develops a sense of exploration, childproofing the environment can be an important precaution to prevent injuries. Families must become knowledgeable in strategies to promote infant safety. This includes information related to car safety, home safety, play safety, water safety, outdoor safety, safety with others, and emergency preparation.\(^6^8\) No home or environment can be completely childproofed, and close supervision of the child by a competent care provider is essential to prevent injury.

Other factors contributing to injury-related infant deaths include motor vehicle accidents. Most states require that infants be placed in an approved infant safety restraint while riding in a vehicle. The middle of the back seat, facing backward toward the back seat of the car, is considered the safest place for the infant to ride.\(^6^9\) Rear-facing car safety seats are recommended for most infants up to 2 years of age or the highest weight or height recommended by the car safety seat manufacturer.\(^6^9\) Many hospitals do not discharge an infant unless there is a safety restraint system in the car. If a family cannot afford a restraint system, programs are available that donate or loan the family a restraint. Health care providers must be involved in educating the public about the dangers of carrying infants in vehicles without taking proper precautions to protect them.

**Infectious Diseases**

One of the most dramatic improvements in infant health has been related to widespread immunization for the major childhood communicable diseases, including diphtheria, pertussis, tetanus, polio, measles, mumps, rubella, hepatitis B, and *Haemophilus influenzae* type B infection. The Advisory Committee on Immunization Practices of the CDC in collaboration with the American Academy of Pediatrics and the American Academy of Family Physicians recommends that United States children receive vaccines against 16 diseases, which includes 21 injections by 18 months of age.\(^6^9\) Immunizations to these infectious diseases have greatly reduced morbidity and mortality in infants and young children. These immunizations are given at standard times as part of health promotion in infants and children. However, although they have lowered their prevalence, immunization programs have not completely eradicated these diseases. Immunization programs are effective only if all children receive the immunizations. Although most immunizations can be received through local health departments at no or low cost, many infants or young children do not routinely receive immunizations or do not receive the full regimen of immunizations. One reason for not immunizing children may be due to public concern that immunizations, specifically those which contain the preservative thimerosal, may cause autism.\(^7^0\) To date, the Institute of
Medicine (IOM) denies that there is any relation between thimerosal-containing vaccines and autism. A scientific review of epidemiologic studies was conducted by the IOM, and the committee concluded that the body of epidemiological evidence favored rejection of a causal relationship between the MMR vaccine and autism.\textsuperscript{7} Therefore, new methods to enhance education related to the benefits of immunizations and strategies to improve access to immunizations are needed. Immunization recommendations are subject to change as research leads to development of improved vaccines or greater understanding of the microorganisms.

**IN SUMMARY**

Infancy is defined as that period from birth to 12 months of age. During this time, growth and development are ongoing. The relative immaturity of many of the organ systems places the infant at risk for a variety of illnesses. Birth initiates many changes in the organ systems as a means of adjusting to postnatal life. Thebirth process is a critical event, and maladjustments and injuries during the birth process are a major cause of death or disability. Premature delivery is a significant health problem in the United States. The premature infant is at risk for numerous health problems because of the interruption of intrauterine growth and immaturity of organ systems.

**EARLY CHILDHOOD**

After completing this section of the chapter, you should be able to meet the following objectives:

- Describe the growth and development of early childhood.
- Discuss the common health problems of early childhood.

Early childhood is considered the period of 12 months through 4 years of age. During this time, the child passes through the stages of toddler (i.e., 12 months to 3 years) and preschooler (i.e., 3 to 5 years).\textsuperscript{5} Many changes occur as the child moves from infancy through the toddler and preschool years. The major achievements are the development and refinement of locomotion and language, which take place as children progress from dependence to independence.

**Growth and Development**

Early childhood is a period of continued physical growth and maturation. Compared with infancy, physical growth is not as dramatic. The average child gains approximately 2 kg in weight and 7 cm in height each year.\textsuperscript{6} The toddler’s abdomen flattens, and the body becomes leaner. Physical energy peaks and the need for sleep declines to 8 to 13 hours a day, usually including one nap.\textsuperscript{6} By 3 years of age, visual acuity reaches 20/30 and all 20 primary teeth have erupted.\textsuperscript{6}

The maturation of organ systems is ongoing during early childhood. The respiratory system continues its growth and maturation, but because of the relative immaturity, shorter length, and small diameters of airway structures, otitis media and respiratory infections are common. Infants and toddlers have barrel-shaped chests and underdeveloped intercostal muscles, which are ineffective in managing periods of respiratory distress.\textsuperscript{6} The respiratory rate of infancy has slowed and averages 20 to 30 breaths/minute. Respirations remain abdominal until 7 years of age.\textsuperscript{6}

Neural growth remains rapid during early childhood. By 12 months of age, the child’s brain is nearly 2/3 of the adult size, and it has doubled in weight since birth.\textsuperscript{6} The cephalocaudal, proximodistal principle is followed by myelination of the cortex, brain stem, and spinal cord is completed. The spinal cord is usually completely myelinated by 2 years of age. At that time, control of anal and urethral sphincters and the motor skills of locomotion can be achieved and mastered. The continuing maturation of the neuromuscular system is increasingly evident as the child gains better control and coordination of body parts.

Growth and maturation in the musculoskeletal system continue with ossification of the skeletal system, growth of the legs, and changes in muscle and fat proportions. Legs grow faster than the trunk in early childhood; after the first year of life, approximately two thirds of the increase in height is leg growth. Muscle growth is balanced by a corresponding decrease in adipose tissue accumulation.

During early childhood, the child masters many important psychosocial tasks. Independence begins to develop, and the child is on the way to becoming a social being in control of the environment. Development and refinement of gross and fine motor abilities allow involvement with a potentially infinite number of tasks and activities. Learning is ongoing and progressive and includes interactions with others, appropriate social behavior, and sex role functions. Psychoanalytic theorist Eric Erikson described the tasks that must be accomplished in early childhood. According to Erickson, the toddler must acquire a sense of autonomy while overcoming a sense of doubt and shame and the preschooler must develop a sense of initiative to overcome a lack of purpose and feelings of guilt.\textsuperscript{67}

**KEY POINTS**

**EARLY CHILDHOOD**

- Early childhood, which encompasses the period from 12 months through 4 years of age, is a period of continued growth and development.
- The major achievements are the development and refinement of locomotion and language, which take place as children progress from dependence to independence.
Common Health Problems

The early childhood years can pose significant health risks to the growing and maturing child. Common health problems that occur during these years include injury, infectious diseases, and child maltreatment.

Injury

Unintentional injuries are the leading cause of death in children between the ages of 1 and 4 years, with drowning being cited as the most prevalent cause for this age group. Locomotion and curiosity, combined with a lack of awareness of danger, place toddlers and preschoolers at special risk for injuries. Incidence of nonfatal injuries, for children between 1 and 19 years of age, is more prevalent among males compared to females. Nonfatal injury rates also vary by age group. Rates for drowning, fires, burns, falls, and poisoning were highest for children 4 years and younger.

Infectious Diseases

Infectious diseases can be a problem for children during early childhood owing to the immaturity of their immune system. This also may be the time when children first enter day care, which increases their exposure to other children and infectious diseases. The major disorders include the communicable childhood diseases (e.g., common cold, influenza, varicella [chicken pox], gastrointestinal tract infections, and otitis media).

Child Maltreatment

Child maltreatment is an increasing problem in the United States. Although the numbers vary according to the methods and definitions used, the best estimates indicate that approximately 3 million reports of maltreatment are made to child welfare agencies each year, and approximately 1 million of the reports are substantiated after investigation. Those at greatest risk for maltreatment are children younger than 4 years of age. These children are the most vulnerable for many reasons, including their dependency, small size, and inability to defend themselves. The most common cause for death in cases of maltreatment include head injury, followed by abdominal injuries, and deliberate suffocation.

Child maltreatment includes physical abuse, emotional abuse, sexual abuse, and neglect. Neglect is the most common type of maltreatment and can take the form of deprivation of basic necessities or failure to meet the child’s emotional needs or abandonment. It is often attributed to poor parenting skills. According to the National Child Abuse and Neglect Data System (NCANDS), 53.8% of child abuse and neglect perpetrators were women and 44.4% were men. Physical abuse is defined as nonaccidental physical injury that is deliberately inflicted by a parent, caregiver, or other who bears responsibility for the child. The cause is probably multifactorial, with predisposing factors that include the parent, child, and environment. Emotional abuse or psychological maltreatment includes methods of verbal abuse, shaming, destruction of child’s personal property, harming or killing child’s pet, and bullying. Sexual abuse is defined as touching of another person without their consent and includes intercourse, sodomy, and fondling. Approximately 80,000 cases are reported annually; however, it is estimated that the number is higher due to the lack of reporting. All types of child maltreatment can lead to lasting effects related to the traumatic experiences. Thus, providing supportive psychological care, fostering a sense of positive self-esteem, and prevention of further abuse are always the goals. In addition, education regarding child maltreatment should be provided to parents during health care provider visits, in an effort to prevent this major childhood health problem.

IN SUMMARY

Early childhood is defined as the period from 12 months through 4 years of age—the toddler and preschool years. Growth and development continue but are not so dramatic as during the prenatal and infancy periods. Early childhood is a time when most organ systems reach maturity and the child becomes an independent, mobile being. There continue to be significant health risks during this period, especially from infectious diseases and injuries. Injuries are the leading cause of death during this period. Child abuse is rapidly increasing as a major health problem.

MIDDLE TO LATE CHILDHOOD

After completing this section of the chapter, you should be able to meet the following objectives:

- Characterize the growth and development that occurs during the early school years.
- Discuss the common health problems of middle to late childhood.

In this text, middle to late childhood is defined as the period in which a child begins school through the beginning of adolescence. These 7 years, between 5 and 12 years of age, involve a great deal of change. When one recollects “childhood,” these are the years most often remembered. The experiences of this period have a profound effect on the physical, cognitive, and psychosocial development of the child and contribute greatly to the adult that the child will become.

Growth and Development

Although physical growth is steady throughout middle childhood, it is slower than in the previous periods and the adolescent period to follow. During late childhood, children...
typically gain approximately 3 kg and grow an average of 6 cm/year.6

During late childhood, a child’s legs grow longer, posture improves, and center of gravity descends to a lower point. These changes, along with increased muscle strength and agility, help children to be successful at climbing, bike riding, roller skating, and other physical activities. Body fat distribution typically decreases and, in combination with the lengthening skeleton, gives the child a thinner appearance. As body fat decreases, lean muscle mass increases. By 12 years of age, boys and girls have doubled their body strength and physical capabilities. Although muscular strength increases, the muscles are still relatively immature. Injury from over strenuous activities, such as difficult sports, can occur. With the gains in length, the head circumference decreases in relation to height, waist circumference decreases in relation to height, and leg length increases in relation to height.

By 6 years of age, the child’s brain has grown significantly and weighs about 90% of its adult size.6 Facial proportions change as the face and jaw grows. Primary teeth (except for the second and third molars) are lost beginning at 5 or 6 years of age and are replaced by permanent teeth throughout the school-age period. When the permanent teeth first appear, they may appear to be too big for the mouth and face. This is a temporary imbalance that is alleviated as the face grows.

Caloric requirements for the younger school-age child (i.e., 5 to 7 years old) are usually lower compared with previous periods and in comparison to the adolescent period to follow. Growth spurts for girls may occur as early as 9 years of age and may occur in boys beginning at 10 or 11 years of age.67 Caloric intake and nutritional requirements increase dramatically with the adolescent growth spurt.

Changes in other body systems are evident during this time period, as well. Heart rate and respiratory rates continue to decrease, and blood pressure gradually rises. Growth of the eye continues, and visual acuity is gradually converted to 20/20 vision by approximately 6 or 7 years of age.65 Bone ossification and mineralization continue to develop with noticeable acceleration of long bone growth.6 Children’s bones cannot resist muscle pressure and pull as well as mature bones. Precautions should be taken to prevent alterations in bone structure, such as providing properly fitting shoes and encouragement to stand erect to prevent poor posture. Children should receive routine health care screenings during this period so that common childhood conditions, such as vision and hearing deficits, obesity, and scoliosis, may be addressed.6

Toward the end of late childhood, the physical differences between the two sexes become apparent (Fig. 2.11). Girls usually enter pubescence approximately 2 years before boys, resulting in noticeable differences in height, weight, and development of secondary sex characteristics. There is much individual variation among children of the same sex. These differences can be extremely difficult for children to cope with.

Entry into the school setting has a major impact on the psychosocial development of the child at this age. The child begins to develop relationships with other children, forming groups. Peers become more important as the child moves out of the security of the family and into the bigger world. Usually during this period, children begin to form closer bonds with individual “best friends.” However, the best friend relationships may frequently change. The personality of the child begins to appear. Although the personality is still developing, the basic temperament and approach to life become apparent. Although changes in personality occur with maturity, the basic elements may not change. The major task of this stage, as identified by Erikson, is the development of industry or accomplishment.6 Failure to meet this task results in a sense of inferiority or incompetence, which can impede further progress.6

**KEY POINTS**

**MIDDLE TO LATE CHILDHOOD**

- Middle to late childhood years (5 to 12 years) are those during which the child begins school through the beginning of adolescence.

**Common Health Problems**

Common health problems seen during middle to late childhood include tooth decay, injury and illness, and overweight and obesity.

**Tooth Decay**

The incidence of dental caries has decreased since the addition of fluoride to most water systems in the United States. Yet the most prominent dental issue in middle childhood is tooth decay.6 The high incidence of dental caries during late
childhood may be related to inadequate dental care and a high amount of dietary sugar. Children at the early part of this stage may not be as effective in brushing their teeth and may require adult assistance, but they may be reluctant to allow parental help. Therefore, health promotion includes teaching about reducing the amount of dietary sugar, proper tooth brushing, and appropriate dental care.

**Injury and Illness**

The chief cause of mortality in this age group is unintentional injury, primarily due to motor vehicle accidents. Specifically, most injury deaths for children between 5 and 19 years of age were due to being an occupant in a motor vehicle accident.\(^7\) Falls are the leading cause for nonfatal injuries in children of all age groups less than 15 years of age.\(^7\) Establishing consistent rules for safe behavior and reinforcing the need to wear protective sports equipment are two essential measures for injury prevention in this age group.

Although childhood cancer is rare, it is the second cause of death for children ages 5 to 14 years of age.\(^7\) The most common types of cancers in children between 0 and 14 years of age are leukemia and brain tumors or CNS malignancies.\(^7\) Prevalence among white children is greater than that among other ethnicities.\(^7\)

Because of the high level of immune system competence in late childhood, these children have an immunologic advantage over earlier years. Immunization against the major communicable diseases of childhood has greatly improved the health of children in their middle childhood years. Yet, children in this age group do experience infections (i.e., viral, bacterial, or fungal) from being in close contact with other children. These infections commonly occur as respiratory, gastrointestinal, or skin diseases. Other acute or chronic health problems may surface for the first time, including epilepsy and developmental or special learning disabilities. In the United States, asthma is the most common chronic disease in children less than 18 years of age.\(^8\)

**Overweight and Obesity**

Overweight and obesity are a national concern for all children in the United States as well as a global epidemic. Overweight in children and adolescents is defined by body mass index (weight in kilograms divided by the square of height in meters) equal to or above the 85th percentile, but lower than the 95th percentile for children of the same age and gender. Obesity is defined as a BMI equal to or above the 95th percentile\(^8\) (Fig. 2.12). Data from the National Health and Nutrition Examination Surveys (2007 to 2008) show that an estimated 16.9% of children and adolescents between 2 and 19 years of age are obese.\(^8\) Findings specific to the school-age child (6 to 11 years old) demonstrated that obesity rates increased from 6.5% between 1976 and 1980 to 19.6% in 2007 to 2008\(^2\) (Table 2.2). Mexican American and non-Hispanic black children and adolescents are disproportionately affected.\(^8\) Over the last two decades, the incidence of obesity for Mexican American adolescent boys has increased from 14.1% to 26.8% in comparison to non-Hispanic black boys who also experienced an increase from 10.7% to 19.8% and non-Hispanic white adolescent boys from 11.6% to 16.7%.\(^8\) Similarly, the incidence of obesity also increased for the girls. The prevalence of obesity for Mexican American adolescent girls has increased from 13.4% to 17.4% in comparison to non-Hispanic black girls who experienced a marked increase from 16.3% to 29.2% and non-Hispanic white adolescent girls from 8.9% to 14.5%.\(^8\)

There are several factors that contribute to childhood overweight/obesity, including genetics, amount of calories consumed in food and drinks, and the amount of energy expended with metabolism, growth, and physical exercise. Evidence is limited regarding specific foods or dietary patterns that contribute to excessive caloric intake in children. However, large portion sizes for food and beverages, eating meals away from home, frequent snacking and consumption of energy-dense foods, and consuming beverages with added calories are often hypothesized as contributing to excessive caloric intake.\(^6\) Participating in physical activity is important for children because of its beneficial effects not only on weight but also on blood pressure and bone strength. Media use, such

Adolescence

After completing this section of the chapter, you should be able to meet the following objectives:

- Characterize the physical and psychosocial changes that occur during adolescence.
- Cite the developmental tasks that adolescents need to fulfill.
- Discuss how the changes that occur during adolescence can influence the health care needs of the adolescent.

Adolescence is a transitional period between childhood and adulthood. It is a period of physical, emotional, and cognitive growth, along with reproductive maturation. The changes of adolescence do not occur on a strict timeline. Instead, they occur at different times according to a unique internal calendar. For definition’s sake, adolescence is considered to begin with the development of secondary sex characteristics, around 11 or 12 years of age, and to end with the completion of somatic growth between approximately 18 and 21 years of age. Girls usually begin and end adolescence earlier than boys. The adolescent period is conveniently referred to as the teenage years.

Several “tasks” that adolescents need to fulfill have been identified. These tasks include achieving independence from parents; adopting peer codes and making personal lifestyle choices; forming or revising individual body image and coming to terms with one’s body image if it is not “perfect”; and establishing sexual, ego, vocational, and moral identities.

Growth and Development

Adolescence is influenced by attainment of developmental milestones related to puberty and influences from family, school, and peers. Physical growth occurs simultaneously as computer and television viewing, may displace the time children spend in physical activity. It may also contribute to increased energy consumption through excessive snacking and eating meals in front of the television. Genetic factors may increase a child’s susceptibility to become overweight.

Pediatric obesity is not just a physical issue. It is also associated with a significant burden of illnesses. Obesity in childhood is linked to obesity in adulthood and does run in families; this places individuals at increased risk for developing diabetes and cardiac disease in later life. Thus, families should be encouraged to plan meal times, provide age-appropriate and healthy food portions, participate in routine physical activity, and limit sedentary behaviors.
with sexual maturation. Most of the physical growth occurs in the truncal area. Age at onset, duration, and extent of the growth varies between boys and girls. In girls, the growth spurt usually begins around 9 to 14 years of age, approximately 2 years ahead of males. It also ends earlier in girls, with less dramatic changes in weight and height. Girls usually gain approximately 2.5 to 20 cm in height and 7 to 25 kg in weight. Most girls have completed their growth spurt by 16 or 17 years of age. Boys begin their growth spurt later, typically at age 13 years, and it usually is more pronounced, with an increase in height of at least 10 cm and an increase in weight of 7 to 30 kg. Boys may continue to gain in height until 18 to 20 years of age.

The changes in physical body size have a characteristic pattern. Growth in arms, legs, hands, feet, and neck is followed by increases in hip and chest size and several months later by increases in shoulder width and depth and trunk length. The period of these rapid and dramatic changes may be difficult for the adolescent and parents. Shoe size may change several times over several months. Although brain size is not significantly increased during adolescence, the size and shape of the skull and facial bones change, making the features of the face appear to be out of proportion until full adult growth is attained. Muscle mass and strength also increase during adolescence. Sometimes, there may be a discrepancy between the growth of bone and muscle mass, creating a temporary dysfunction with slower or less smooth movements resulting from the mismatch of bone and muscle. Body proportions undergo typical changes during adolescence. In boys, the thorax becomes broader, and the pelvis remains narrow. In girls, the opposite occurs: the thorax remains narrow, and the pelvis widens.

Organ systems also undergo changes in function, and some have changes in structure. The heart increases in size as the result of increased muscle cell size. Heart rate decreases to normal adult rates, whereas blood pressure increases rapidly to adult rates. Circulating blood volume and hemoglobin concentration increase. Boys demonstrate greater changes in blood volume and higher hemoglobin concentrations because of greater androgenic stimulation of the bone marrow.

Skin becomes thicker and additional hair growth occurs in both sexes. Sebaceous and sweat gland activity increases. Adrenal production of androgens stimulates the sebaceous glands, which contributes to the development of acne. Increased sweat gland activity results in perspiration and body odor. Voice changes are of significant importance during adolescence for both sexes. However, the change is more pronounced in boys. The voice change results from growth of the larynx, pharynx, and lungs. Greater growth occurs in the larynx of boys than in girls. The paranasal sinuses reach adult proportions, which increases the resonance of the voice, adding to the adult sound of the voice. Dental changes include jaw growth, loss of the final deciduous teeth, and eruption of the permanent cuspids, premolars, and molars. Orthodontic appliances may be needed.

The endocrine system plays a primary role in the changes throughout adolescence. Triggers that initiate the process are not completely understood. However, the result of adrenal maturation reveals physical changes in the adolescent body, such as the development of pubic and axillary hair, increased oils in the skin and hair, acne, and body odors. Another physiologic process that occurs is maturation of the hypothalamic–pituitary–gonadal axis, which is responsible for increases in circulating gonadal sex steroids. Once gonadal steroid hormones are secreted at an elevated rate, overt signs of puberty are easily identified. In girls, initial signs of puberty can be seen with breast development, followed by pubic hair, and then menses approximately 2 to 2.5 years later, in conjunction with attainment of peak height.

Puberty begins later for boys, with testicular enlargement, followed by penile growth, and then the development of pubic hair. Boys may also experience spontaneous erections or nocturnal seminal emissions, as a normal development of puberty. During this period, both genders will grow 3 to 4 inches over a 2-year period.

In addition to reproduction maturation, changes also occur within the cortical and limbic circuits of the brain. The link between these two processes is that the brain is a target organ for steroid hormones. Essentially, neuroscientists have hypothesized that there exists a “coupling” in adolescent development between the brain and puberty hormones. As cortical and limbic circuits remodel, cognition and decision-making processes are further developed, along with social behaviors. Although more research is necessary in order to enhance knowledge regarding this relationship, scientists have raised questions as to what variables and interactions occur between pubertal hormones, brain development, cognition, and behavioral maturation during the adolescent period.

The behavioral and psychosocial changes that occur during adolescence are comparable to the physical changes. It is not possible to develop one guide that adequately describes and explains the tremendous changes that occur during adolescence because the experience is unique for each adolescent. There are, fortunately, some commonalities within the process that can be used to facilitate understanding of these changes. The transition from child to adult is not a smooth, continuous, or uniform process. There are frequent periods of rapid change, followed by brief plateaus. These periods can change with little or no warning, which makes living with an adolescent difficult at times.

There is one thing that people who deal with adolescents must remember: no matter how rocky the transition from child to adult, adolescence is not a permanent state. The majority of adolescents go through adolescence with few or no lasting difficulties. Health care professionals who care for adolescents may need to offer support to worried parents that the difficulties their adolescent is experiencing, and that the entire family is experiencing as a result, may be normal. The adolescent also may need reassurance that his or her feelings are not abnormal.
Common concerns of adolescents include conflicts with parents, conflicts with siblings, concerns about school, and concerns about peers and peer relationships. Personal identity is an overwhelming concern expressed by adolescents.

Parents of adolescents also may have concerns about their child. Common concerns related to the adolescent’s behavior include rebelliousness, wasting time, risk-taking behaviors, mood swings, drug experimentation, school problems, psychosomatic complaints, and sexual activity. Adolescence is a period of transition from childhood to adulthood, and it is often filled with conflicts as the adolescent attempts to take on an adult role. Open communication between the adolescent and family can help make the transition less stressful. However, communication between parents and adolescents can be challenging.

Common Health Problems

Adolescence is considered to be a relatively healthy period. However, significant morbidity and mortality do occur. Common health problems experienced by adolescents include headache, eating disorders, weight loss/weight gain, and insomnia. These disorders may be psychosomatic in origin. The health care worker may need to refer adolescents for specialized counseling or medical care if any of these health care concerns are exaggerated.

Additional health problems during the adolescent years (discussed below) include injury, suicide, cancer, risky sexual behaviors and adolescent pregnancy, and substance abuse, including drug and alcohol abuse and tobacco use. Health promotion is of extreme importance during the adolescent period.

Injury

There are fewer actual physical health problems during the adolescent period, but there is a greater risk of morbidity and mortality from unintentional injuries. According to the Federal Interagency Forum on Child and Family Statistics, approximately 70% of injury deaths among adolescents were related to either motor vehicle traffic (21 per 100,000) or firearms (12 per 100,000). Additionally, homicides accounted for 21% of injury deaths and 14% were attributed to suicide.

While the leading cause of adolescent mortality is due to unintentional injuries, the incidence of nonfatal injuries is also prevalent. Nonfatal injuries most often result from being struck by or against an object or person, due to violence, sports-related activities, or motor vehicle accidents. Many of the injuries could be prevented with the use of simple safety measures, including automobile seat belts and bicycle and motorcycle helmets.

Several factors contribute to the risk for injury during adolescence. The adolescent often is unable to recognize potentially dangerous situations, possibly because of a discrepancy between physical maturity and cognitive and emotional development. Certain behavioral and developmental characteristics of the adolescent exaggerate this problem. Adolescents typically feel the need to challenge parental or other authority. They also have a strong desire to “fit in” with the peer group. Adolescents exhibit a type of risk-taking behavior and have a need to experiment with potentially dangerous situations or behaviors. They believe that bad things will not happen to them, despite engaging in risky behaviors.

Suicide

Another major cause of death in this age group is suicide. Even though the number of adolescents reporting suicidal thoughts has decreased in the past decade, the number of suicide attempts has remained constant. Risk factors for suicide in adolescents include substance abuse, personal or family history of depression, anxiety disorders, problems at school, problems communicating with parents, having a friend or peer who committed suicide, and family ownership of a handgun.

Cancer

The fourth major cause of death in adolescents and the young adult, ages 15 to 24, is due to cancer. There is an increased incidence of certain types of cancer during adolescence. According to the National Cancer Institute, the highest incidence of cancer in adolescents between 15 and 19 years old includes lymphoma, germ cell tumors in males (i.e., testicular cancer), and carcinomas (thyroid) in females, followed by leukemia.

Risky Sexual Behavior and Adolescent Pregnancy

The increasing prevalence of sexual activity among adolescents has created unique health problems. These include adolescent pregnancy, sexually transmitted infections, and human immunodeficiency virus (HIV) transmission. Associated problems include substance abuse, such as alcohol, tobacco, inhalants, and other illicit drugs. Health care providers must not neglect discussing sexual activity with the adolescent. Nonjudgmental, open, factual communication is essential for dealing with an adolescent’s sexual practices. Discussion of sexual activity frequently is difficult for the adolescent and the adolescent’s family. If a relationship
exists between the adolescent and the health care provider, this may provide a valuable forum for the adolescent to get accurate information about safe sex, including contraception and avoidance of high-risk behaviors for acquiring sexually transmitted infections or acquired immunodeficiency syndrome (AIDS).  

The past few decades demonstrate an overall decline in adolescent pregnancies since 1991, except for a brief rise from 2005 to 2007.  

However, adolescent pregnancy remains a chief health concern because of the frequently associated long-term challenges for the parent and the child. Preliminary results from the National Center for Health Statistics, National Vital Statistics System (2011), state that 94% of births to females ages 15 to 17 were to unmarried mothers.  

Among this at risk group, racial and ethnic disparities exist. In 2009, Hispanic adolescent females between 15 and 17 years of age had the highest rate of pregnancies at 41.0 per 1000 births, followed by Black, non-Hispanics at 32.1, and American Indians or Alaskan Natives at 30.6.  

Risks for single teenage mothers are associated with lack of supportive networks and cognitive stimulation, socio-economic difficulties, and decreased rates of high school graduation. Additionally, risks for infants born to young mothers include increased incidence of LBW and infant mortality.  

The topic of adolescent pregnancy involves issues related to physical and biologic maturity of the adolescent, growth requirements of the adolescent and fetus, and unique prenatal care requirements of the pregnant adolescent. Emotional responses and psychological issues regarding relationships of the adolescent in her family and with the father of the infant, as well as how the pregnancy will affect the adolescent’s future, must be considered.  

**Substance Abuse**  
Substance abuse among adolescents increased rapidly during the 1960s and 1970s but has declined since that time. However, substance abuse still is prevalent in the adolescent age group. Results from a recent national survey among 9th to 12th grade students report the following: 20% smoked cigarettes on at least 1 day during the 30 days before the survey, 42% had at least one drink of alcohol on at least 1 day during the 30 days before the survey, and 21% used marijuana once or more times during the 30 days before the survey.  

These results support that many lifelong users of tobacco and alcohol begin using substances during adolescence. Early experimentation can lead to a life of addiction or abuse. Research has described an association between age of alcohol use and increase in alcohol problems (dependence and abuse) later in life. Health care workers must be knowledgeable about the symptoms of drug abuse, the consequences of drug abuse, and the appropriate management of adolescents with substance abuse problems. Substance abuse among adolescents includes the use of tobacco products, particularly cigarettes and “smokeless” tobacco (e.g., snuff, chewing tobacco), alcohol, marijuana, stimulants, inhalants, cocaine, hallucinogens, tranquilizers, and sedatives. Adolescents are at high risk for succumbing to the peer pressure to participate in substance abuse. They have a strong desire to fit in and be accepted by their peer group. It is difficult for them to “just say no.” Risk-taking behaviors lead adolescents to believe that they will not get “hooked” or that the bad consequences will not happen to them. It is important that adolescents be provided with “the rest of the story” through education and constant communication with parents, teachers, role models, health care providers, and others who may have a positive influence on the adolescent.  

Adolescence is a transitional period between childhood and adulthood. It begins with development of secondary sex characteristics (11 to 12 years) and ends with cessation of somatic growth (18 to 21 years). This is the period of a major growth spurt, which is more pronounced in boys. The endocrine system is of great importance, with its numerous hormonal changes and their initiation and continuation of the growth spurt. Psychosocial changes are equally dramatic during this period and often place tremendous pressure on relationships between adults and the adolescent. Adolescence is a relatively healthy period, but significant morbidity and mortality exist as a result of accidents, homicide, and suicide. The prevalence of sexual activity and substance abuse places the adolescent at risk for HIV infection; alcohol, tobacco, and other drug abuse; and adolescent pregnancy.  

---

**IN SUMMARY**  
Adolescence is a transitional period between childhood and adulthood. It begins with development of secondary sex characteristics (11 to 12 years) and ends with cessation of somatic growth (18 to 21 years). This is the period of a major growth spurt, which is more pronounced in boys. The endocrine system is of great importance, with its numerous hormonal changes and their initiation and continuation of the growth spurt. Psychosocial changes are equally dramatic during this period and often place tremendous pressure on relationships between adults and the adolescent. Adolescence is a relatively healthy period, but significant morbidity and mortality exist as a result of accidents, homicide, and suicide. The prevalence of sexual activity and substance abuse places the adolescent at risk for HIV infection; alcohol, tobacco, and other drug abuse; and adolescent pregnancy.
3. A 10-year-old boy is seen in the clinic for a routine physical examination. His weight is 50 kg, and his height is 149 cm. His mother complains that he is constantly watching television or playing video games and seems to have no interest in riding his bike or participating in physical sports. Furthermore, he is constantly snacking and drinking sugar-sweetened cola drinks.

A. Use the CDC’s online child and teen body mass index (BMI) calculator http://apps.nccd.cdc.gov/dnpabmi/ to calculate this boy’s BMI and determine whether he is overweight.

B. What suggestions might you provide for this boy and his mother?

4. An adolescent boy is seen in the health clinic for a routine sports examination. The nurse practitioner notes that the adolescent has a mild to moderate case of facial acne. The nurse practitioner discusses the causes, prevention, and treatment of acne with the young man.

A. What physiologic changes contribute to the development of acne in adolescents?

B. What other physical changes also occur during adolescence?

C. What are common health problems in adolescents?

Old age is not a disease—it is strength and survivorship, triumph over all kinds of vicissitudes and disappointments, trials and illnesses.

—MAGGIE KUHN

Aging is a natural, lifelong process that brings with it unique biopsychosocial changes. For many older adults, there are changes in bodily function, physical appearance, cognitive abilities, family structure, and social environment. Gerontology is the discipline that studies aging and the aged from biologic, psychological, and sociologic perspectives. It explores the dynamic processes of complex physical changes, adjustments in psychological functioning, and alterations in social identities.

An important first distinction is that aging and disease are not synonymous. Unfortunately, a common assumption is that growing older is inevitably accompanied by illness, disability, and overall decline in function. The fact is that the aging body can accomplish most, if not all, of the functions of its youth. The difference is that functions may take longer, require greater motivation, and be less precise. However, as in youth, maintenance of physiologic function occurs through continued use.
national pension system in the United States, which designated 65 years as the pensionable age, was developed. Since then, the expression old age has been understood to apply to anyone older than 65 years. Because there is considerable heterogeneity among this group, older adults often are sub-grouped into young-old (65 to 74 years), middle-old (75 to 84 years), and old-old (85+ years) to reflect more accurately the changes in function that occur. Age parameters, however, are somewhat irrelevant because chronologic age is a poor predictor of biologic function. However, chronologic age does help to quantify the number of people in a group and allows predictions to be made for the future.

In the year 2009, nearly 13% of the total US population (39.5 million) was 65 years of age or older. The proportion of older adults declined for the first time in the 1990s, partly because of the relatively low number of births in the late 1920s and early 1930s. This trend stopped in 2010 when the “baby boomers” (i.e., people born from 1946 to 1964) started to reach age 65.

The older adult population itself is getting older. Average life expectancy has increased as a result of overall advances in health care technology, improved nutrition, and improved sanitation. In 2008, the 65- to 74-year-old age group (20.8 million) was over 9.5 times larger than in 1900, whereas the 75- to 84-year-old group (13.1 million) was 17 times larger and the 85-year-old and over group (5.6 million) was nearly 46 times larger. The entire population of older adults is expected to grow to about 72 million by the year 2030 (Fig. 3.1). Women who are now 65 years of age can expect to live an additional 19.9 years (97.8 years of age) and men an additional 17.2 years (90.1 years of age).

Women tend to outlive men throughout the aging process. In 2009, there was a sex ratio of 136 women for every 100 men older than 65 years in the United States. This ratio increases to as high as 216 women for every 100 men in the 85 years and older age group. Marital status also changes with advancing age. In 2009, almost half of all older women were widows, and there were three times as many widows as there were widowers.

Although about 6.5 million older adults were in the workforce in 2009 (i.e., working or actively seeking work), most were retired. Retirement represents a significant role change for older adults. Attitudes and adjustment to retirement are influenced by preretirement lifestyles and values. People with leisure pursuits during their work life seem to adjust better to retirement than those whose lives were dominated by work. For many of today’s older adults, especially the old-old, the work ethic of the Great Depression remains profoundly ingrained as the central purpose in life. When work is gone, a significant loss is felt, and something must be substituted in its place. Because leisure has not always been a highly valued activity, older adults may have difficulty learning to engage in meaningful leisure pursuits.

Loss of productive work is just one of many losses that can accompany the aging process. Loss of a spouse is a highly significant life event that commonly has negative implications for the survivor. Experts cite an increased mortality rate among recently bereaved older adults (especially men); an increased incidence of depression, psychological distress, and loneliness; and higher rates of chronic illness. Loss of physical health and loss of independence are other changes that can affect the psychosocial aspects of aging, as can relocation, loss of friends and relatives, and changes in the family structure. Poverty is common among

**FIGURE 3.1** Chart of population 65 and older by age: 1900 to 2050. This chart shows the large increase in the population 65 and older from 3.1 million people in 1900 to 35 million in 2000 and projected to 72 million in 2030. (Sources: Projections for 2010 through 2050 are from Table 12. Projections of the Population by Age and Sex for the United States: 2010 to 2050 (NP2008-T12), Population Division, U.S. Census Bureau; Release Date: August 14, 2008. The source of the data for 1900 to 2000 is Table 5. Population by Age and Sex for the United States: 1900 to 2000, Part A. Number, Hobbs, Frank and Nicole Stoops, U.S. Census Bureau, Census 2000 Special Reports, Series CENSR-4, Demographic Trends in the 20th Century. This table was compiled by the U.S. Administration on Aging using the Census data noted.)
the older adult population. In 2009, 8.9% of those 65 years of age and older lived below the poverty line, and another 5.4% were classified as “near poor” (income between the poverty level and 125% of this level). Poverty rates vary among older adult subgroups, with 19.5% of African American, 18.3% of Hispanics, and 6.5% of Whites being at the poverty level in 2009. The main sources of income for older people in 2008 were Social Security (87% of older people), income from assets (54.6%), public and private pensions (28%), and earnings (25%).

Contrary to popular belief, most older adults live in community settings. Most live in some type of family setting, with a spouse, their children, or other relatives, and approximately 30% live alone. Only 4.1% of all adults 65 years of age and older reside in long-term care facilities or nursing homes. However, this number increases to 14.3% for people 85 years of age or older. In addition, about 2.4% of older adults live in various types of senior housing, many of which have supportive services available to their residents.

In 2009, 37% of older adults reported having one or more disabilities. In the 80+ population, over 50% have at least one severe disability, and approximately one quarter of community-dwelling older adults have difficulties performing activities of daily living (ADLs). Almost half of all adult hospital beds are filled with people 65 years of age and older.

**Theories of Aging**

Multiple theories have attempted to explain the biology of aging through a variety of scientific observations at the molecular, cellular, organ, and system levels. In general, these theories can be divided into either extrinsic (stochastic) or intrinsic (nonstochastic, developmental–genetic theories). Stochastic theories postulate that the changes result from an accumulation of random events or damage from environmental agents or influences. Nonstochastic theories propose that the changes that occur with aging are genetically programmed. In reality, evidence suggests that the process of aging and longevity is multifaceted, with both genetics and environmental factors playing a role. In humans, a very long life, to beyond 90 years of age, appears to have a stronger genetic basis. This explains why centenarians and near-centenarians tend to cluster in families.

**Stochastic Theories**

The stochastic theories propose that aging is caused by random damage to vital cell molecules (e.g., mitochondrial deoxyribonucleic acid [DNA] damage, nuclear DNA cross-linking). The damage eventually accumulates to a level sufficient to result in the physiologic decline associated with aging.

The somatic mutation theory of aging states that the longevity and function of cells in various tissues of the body are determined by the double-stranded DNA molecule and its specific repair enzymes. DNA undergoes continuous change in response to both exogenous agents and intrinsic processes. Aging may result from conditions that produce mutations in DNA or deficits in DNA repair mechanisms.

The oxidative free radical theory is another stochastic idea in which aging is thought to result partially from oxidative metabolism and the effects of free radical damage. The major by-products of oxidative metabolism include superoxides that react with DNA, ribonucleic acid, proteins, and lipids, leading to cellular damage and aging. Another damage theory, the wear-and-tear theory, proposes that accumulated damage to vital parts of the cell leads to aging and death. Cellular DNA is cited as an example. If repair to damaged DNA is incomplete or defective, as is thought to occur with aging, declines in cellular function might occur.

**Nonstochastic Theories**

The developmental–genetic theories focus on the genetic influences that determine physical condition, occurrence of disease, age of death, cause of death, and other factors contributing to longevity. At the cellular level, Hayflick and Moorhead observed more than 40 years ago that cultured human fibroblasts have a limited ability to replicate (approximately 50 population doublings) and then die. This is known as the Hayflick limit. Before achieving this maximum, they slow their rate of division and manifest identifiable and predictable morphologic changes characteristic of senescent cells.

Another explanation of cellular aging resides with an enzyme called telomerase that is believed to govern somatic aging through its action on telomeres, the outermost extremities of the chromosome arms. With each cell division, a small segment of telomeric DNA is lost, unless a cell has
a constant supply of telomerase. In the absence of telomerase, the telomeres shorten, resulting in senescence-associated gene expression and inhibition of cell replication. It is thought that in certain cells, such as cancer cells, telomerase maintains telomere length, thereby enhancing cell replication.1

Many genes that are associated with the human life span are not “longevity genes,” per se. For example, because mutations in the tumor suppressor genes BRCA1 and BRCA2 increase mortality rates associated with breast and ovarian cancer, they are rare among long-lived women.12 Genetic studies of biologic aging have explored the involvement of allelic variants in genes encoding apolipoproteins, in particular, that of apolipoprotein E (apoE). The presence of apoE4 is associated with increased incidence of cardiovascular diseases and neurodegenerative diseases, thereby shortening the life span through disease processes.13–15 Conversely, genes that reduce the risk of atherosclerosis may be more common in long-lived people.

### IN SUMMARY

Aging is a natural, lifelong process that brings with it unique biopsychosocial changes. Aging is not synonymous with disease or ill health. The aging body can accomplish most or all of the functions of its youth. However, these functions may take longer, require greater motivation, and be less precise.

The older adult population is typically defined in chronologic terms as people 65 years of age and older. It is further defined as young-old (65 to 74 years), middle-old (75 to 84 years), and old-old (85+ years). The number of older adults has increased and is expected to continue to grow in the future, with an anticipated 72 million Americans older than 65 years of age by the year 2030.

There are two main types of theories used to explain the biologic changes that occur with aging—stochastic theories, which maintain that aging changes result from an accumulation of random events or damage from environmental hazards, and developmental-genetic theories, which propose that aging changes are genetically programmed.

### PHYSIOLOGIC CHANGES OF AGING

After completing this section of the chapter, you should be able to meet the following objectives:

- Describe the process of bone loss that occurs with aging.
- State the common changes in blood pressure regulation that occur with aging.
- Describe changes that occur in the gastrointestinal tract with aging.
- State the significance of decreased lean body mass on interpretation of the glomerular filtration rate (GFR) using serum creatinine levels.

The physiologic changes seen in older adults reflect not only the aging process but the effects of years of exposure to environmental agents such as sunlight and cigarette smoke and disease processes such as diabetes mellitus or arthritis. Overall, there is a general decline in the structure and function of the body with advancing age (Fig. 3.2). The decline results in a decreased reserve capacity of the various organ systems that subsequently produce reduced homeostatic capabilities, making the older adult more vulnerable to stressors such as illness, trauma, surgery, medications, and environmental changes.

Research to identify true age-related changes as opposed to disease states is difficult. Studies using cross-sectional methodologies are the easiest to perform. However, mortality can confound the results. Although longitudinal studies tend to be more precise, they require years to perform and may not be able to account for numerous variables that enter into the aging equation, such as environment, occupation, and diet. However, it is important to differentiate, as much as possible, those changes that occur in the body as a result of aging from those that occur owing to disease. This distinction allows for more accurate diagnosis and treatment of disease conditions and helps to avoid inappropriate labeling of aging changes.

Regardless of the difficulty in defining normal aging as it relates to the various organ systems, there is a pattern of gradual loss that occurs. Many of these losses begin in early adulthood, but because of the large physiologic reserve of most organ systems, the decrement does not become functionally significant until the loss reaches a certain level. Some changes, such as those that affect the skin and posture, are more visible. Others, such as those affecting the kidney, may go unnoticed until the person is challenged with situations such as eliminating medications.

### Integumentary Changes

Changes in the skin more obviously reflect the aging process than do changes in other organ systems. Aging can impinge on the primary functions of the skin—protection from the environment, temperature regulation, fluid and electrolyte balance, sensory function, and excretion of metabolic wastes. Exposure to sunlight and harsh weather accelerates aging of the skin.

With aging, the skin becomes wrinkled and dry and develops uneven pigmentation. The thickness of the dermis, or middle layer of skin, decreases by approximately 20%, which gives the skin an overall thin and transparent quality. This is especially true for areas exposed to sunlight. Dermal collagen fibers rearrange and degenerate, resulting in decreased skin strength and elasticity.6,16 Cellularity and vascularity of the dermis decrease with advancing age and can cause vascular fragility, leading to senile purpura (i.e., skin hemorrhages) and slow skin healing. Delayed wound healing may be influenced by other factors such as poor nutrition and circulation and by changes in immune function.17 The function of the sebaceous glands diminishes with age and leads to a decrease in sebum secretion. The decrease in size, number, and activity of the eccrine sweat glands causes a decrease in their capacity to
Neuromuscular function
- Loss of neurons, atrophy of neuronal dendrites, impaired synaptic connections
- Declined motor strength, slowed reaction time, diminished reflexes
- Decrease in proprioceptor function that controls balance

Cardiovascular function
- Increased stiffness of blood vessels
- Decreased responsiveness to catecholamines
- Decrease in exercise heart rate
- Decrease in diastolic ventricular relaxation

Immune function
- Altered function of helper T cells
- Diminished immune response

Stature and musculoskeletal changes
- Decrease in height
- Loss of bone mass
- Decrease in muscle strength
- Skeletal bone loss

Integumentary function
- Thin, dry skin
- Decreased sebum and sweat
- Thick and brittle nails
- Sparse, gray hair

Special senses
- Decline in visual acuity
- Hearing loss
- Decline in smell

Respiratory function
- Decrease in VO₂ max
- Progressive loss of elastic recoil in lungs and chest wall
- Decrease in PO₂

Gastrointestinal function
- Dental problems
- Dry mouth
- Mucosal atrophy
- Constipation

Renal function
- Decrease in functional glomeruli
- Decline in renal blood flow
- Decreased glomerular filtration rate
- Decreased urine concentration ability

Genitourinary function
- Decreased bladder capacity, incomplete emptying
- Increased incidence of incontinence
- Decreased serum testosterone levels in men
- Increased vaginal dryness in women
- Decreased sexual response

Mrs. Sora had a burning sensation on the left side of her back where a rash developed a few days later. This combination of a tingling/burning feeling on one side of the body followed by a rash of small fluid-filled blisters is known as herpes zoster, or shingles, and is commonly seen in older people. It is a reactivation of the chicken pox virus (varicella zoster virus) and occurs along a nerve pathway. What makes it unique is that it only occurs on one side of the body. Some people are left with pain in the area of the rash long after it has healed. The reason for reactivation of the virus is not clear, but it seems to be linked to stress and immune suppression.
Stature and Musculoskeletal Function

Aging is accompanied by a progressive decline in height, especially among older women. This decline in height is attributed mainly to compression of the vertebral column.20 Body composition changes as well. The amount of fat increases, and lean body mass and total body water decrease with advancing age.

With aging, there is a reduction in muscle size and strength that is related to a loss of muscle fibers and a reduction in the size of the existing fibers. Although the decline in strength that occurs with aging cannot be halted, its progress can be slowed with exercise. There is a decline in high-speed performance and reaction time because of a decrease in type II muscle fibers.21 Impairments in the nervous system also can cause movements to slow. However, type I muscle fibers, which offer endurance, are thought to remain consistent with age.

Numerous studies have reported a loss of bone mass with aging, regardless of sex, race, or body size. With aging, the process of bone formation (i.e., renewal) is slowed in relation to bone resorption (i.e., breakdown), resulting in a loss of bone mass and weakened bone structure.21,22 This is especially true for postmenopausal women. After menopause, there is a rapid decline in bone mass due to estrogen deficiency. This bone loss continues into later life. There are data to suggest that older men lose bone at rates similar to those of older women.23 This process becomes pathologic (i.e., osteoporosis) when it significantly increases the predisposition to fracture and associated complications.

The prevalence of joint disease is increased among older adults. By age 65 years, 80% of the population has some arthritic disease. Osteoarthritis is so common among older adults that it is often incorrectly assumed to be a normal age-related change rather than a disease. The synovial joints ultimately are affected by osteoarthritis, most commonly the joints of the hands, feet, knees, hips, and shoulders. It is characterized by cartilage loss and new bone formation, accounting for a distortion in articulation, limited range of motion, and joint instability.21,24 Age is the single greatest risk factor for development of osteoarthritis, in part because of the mechanical impact on joints over time, but it also is related to injury, altered physical condition of the articular cartilage, obesity (e.g., knee), congenital deformity (e.g., hip), crystal deposition in articular cartilage (e.g., knee), and heredity. Pain, immobility, and joint inflammation often ensue. Treatment is aimed at minimizing risk factors, weight loss if indicated, exercise to increase muscle strength, and pain relief measures.

Cardiovascular Function

Cardiovascular disease remains the leading cause of morbidity and mortality in older adults. It often is difficult to separate true age-related changes in the cardiovascular system from disease processes. The aorta and arteries tend to become stiffer and less distensible with age, the heart becomes less responsive to the catecholamines, the maximal exercise heart rate declines, and there is a decreased rate of left ventricular diastolic relaxation.

Blood Pressure

The relationship between blood pressure and risk of cardiovascular disease is continuous, consistent, and independent of other risk factors. Numerous studies have shown that systolic blood pressure progressively increases with age, whereas increases in diastolic blood pressure tend to plateau and even decline after age 50.6,25 As a result, there is a sharp increase in what is known as systolic hypertension among older adults, which occurs as a consequence of increased arterial stiffness.26

An elevation in systolic blood pressure accompanied by a normotensive diastolic pressure causes a dramatic increase in pulse pressure. This is a known prognostic indicator for future coronary events. Thus aggressive treatment of systolic hypertension is recommended and has been shown to demonstrate a reduction in stroke, heart failure, kidney disease, and other complications.26,27 People who are normotensive at 55 years of age have a 90% lifetime risk for development of hypertension.28 There is now a push to intervene when people are prehypertensive (i.e., systolic blood pressure of 120 to 139 mm Hg or diastolic blood pressure of 80 to 89 mm Hg) with lifestyle modification strategies to prevent hypertension.29

Orthostatic hypotension, or a significant drop in systolic pressure on assumption of the upright position, is more common among older adults. Compensatory cardiovascular mechanisms often are delayed or insufficient, so that a drop in blood pressure due to position change or consumption of a meal is also common.30 Even in the absence of orthostatic hypotension, older adults respond to postural stress with diminished changes in heart rate and diastolic pressure. This altered response to orthostatic stress is thought to result from changes in autonomic nervous system function, inadequate functioning of the circulatory system, or both.31

Cardiac Function

Multiple factors determine the effect of aging on cardiac function in healthy older adults. With aging, there is an increase in left ventricular wall thickness, a delay in early left ventricular filling, a decrease in responsiveness to β-adrenergic stimulation and circulating catecholamines, a decrease in the maximal heart rate and maximal cardiac output, and an increase in systemic vascular resistance and left ventricular afterload. The afterload (i.e., opposition to left ventricular ejection) rises steadily with age as the ascending aorta becomes more rigid and the resistance in peripheral arterial vessels increases.25 Although the overall size of the heart does not increase, the thickness of the left ventricular wall may increase with age, in part responding to the increased afterload that develops because of blood vessel changes.30

Both left ventricular diastolic and systolic function are affected by aging. Although early diastolic filling decreases by approximately 50% between 20 and 80 years of age, more filling occurs in late diastole, in part because of more vigorous atrial contraction.25 The augmented atrial contraction is
accompanied by atrial hypertrophy and enlargement. Despite a decrease in the age-associated changes in the diastolic filling pattern in older people, their left ventricular end-diastolic volume in the supine position does not substantially differ from that of younger people. However, it is reduced to a lesser extent in older people than in younger people during postural change (moving from the supine to seated position) and during graded upright exercise. Furthermore, the maximum left ventricular ejection fraction (i.e., percentage of the left ventricular end-diastolic volume that is ejected during systole) that can be achieved during maximal exercise decreases with age—in this case because of a lesser decrease in left ventricular end-systolic volume. An age-associated decline in myocardial contractility is thought to contribute to this defect in end-systolic volume regulation.

The supine resting heart rate remains unchanged or decreases only slightly with age. However, the maximum heart rate that can be achieved during maximal exercise is decreased. The reduction in heart rate is the reason why the maximum cardiac output reserve decreases in healthy older adults.

Despite aging changes and cardiovascular disease, overall cardiovascular function at rest in most healthy older adults is considered adequate to meet the body’s needs. Cardiac output is essentially maintained in healthy older adults (men more than women) during exercise despite the decreased heart rate response, apparently because of a greater stroke volume resulting from increased end-diastolic volume during exercise.

The cardiac conduction system undergoes changes as well. The sinoatrial node experiences fibrosis and the number of sinus node pacemaker cells are reduced by about 90%. The atrioventricular node may be affected by nearby calcification of cardiac muscle. Consequences of these changes include “sick sinus syndrome” and conduction abnormalities.

Respiratory Function

As lung function changes with age, it often is difficult to differentiate the effects of age from those of environmental and disease factors. Maximal oxygen consumption (VO₂max), a measure used to determine overall cardiopulmonary function, declines with age. Numerous studies have indicated that VO₂max can improve significantly with exercise and that the VO₂max of older adult master athletes can meet that of their younger counterparts.

Loss of elastic recoil in the lung is not caused by changes in the amount of elastin and composition of collagen fibers. Rather, increase in alveolar diameter decreases surface tension, thereby decreasing the elastic recoil. Calcification of the soft tissues of the chest wall causes increased stiffness and thus increases the workload of the respiratory muscles. There is a loss of alveolar structure that decreases the surface area of gas exchange. Although the total lung capacity remains constant, the consequences of these changes result in an increased residual lung volume, an increased functional reserve capacity, and a decline in vital capacity. There is a linear decrease in arterial oxygen tension (PO₂) of approximately 20 mm Hg from 20 to 70 years of age. This is thought to result primarily from the ventilation–perfusion mismatching of the aging lung.

Neurologic Function

Changes at the structural, chemical, and functional levels of the nervous system occur with normal aging, but overall they do not interfere with day-to-day routines unless specific neurologic diseases come into play. The weight of the brain decreases with age, and there is a loss of neurons in the brain and spinal cord. Neuron loss is most pronounced in the cerebral cortex, especially in the superior temporal area. Additional changes take place in the neurons and supporting cells. Atrophy of the neuronal dendrites results in impaired synaptic connections, diminished electrochemical reactions, and neural dysfunction. Synaptic transmissions also are affected by changes in the chemical neurotransmitters dopamine, acetylcholine, and serotonin. As a result, many neural processes slow. Lipofuscin deposits (i.e., yellow, insoluble intracellular material) are found in greater amounts in the aged brain.

Sensorimotor changes show a decline in motor strength, slowed reaction time, diminished reflexes (especially in the ankles), and proprioception changes. These changes can cause the balance problems and slower, more deliberate movements that are frequently seen in older adults.

Even though changes in the brain are associated with aging, overall cognitive abilities remain intact. Although language skills and attention are not altered with advanced age, performance and constructional task abilities can decline, as can short-term memory and immediate recall. A change in personality or significant cognitive deficits is considered unusual with normal aging, and if either occurs, evaluation is in order. Dementia or depression can frequently be the cause.

Special Sensory Function

Sensory changes with aging can greatly affect the older adult’s level of functioning and quality of life. Vision and hearing impairments due to disease states, for example, can interfere with communication and may lead to social isolation and depression.

Vision

There is a general decline in visual acuity with age, and nearly all people older than 55 years of age require vision correction for reading or distance. The decline occurs as a result of a smaller pupil diameter, loss of refractive power of the lens, and an increase in the scattering of light. The most common visual problem among older adults is presbyopia, or difficulty focusing on near objects. It is caused mainly by decreased elasticity of the lens and atrophy of the ciliary muscle.

Glare and abrupt changes in light pose particular problems for older adults. These changes increase the risk for falls and injury. In addition, both are reasons why older adults frequently give up night driving. Color discrimination changes also take place with aging. In particular, older adults have
more difficulty identifying blues and greens. This is thought to be related to problems associated with filtering short wavelengths of light (i.e., violet, blue, green) through a yellowed, opaque lens. Corneal sensitivity also may diminish with age, so that older adults may be less aware of injury or infection.39

Ophthalmologic diseases and disorders are common in older adults. Cataracts, glaucoma, and macular degeneration are frequently seen and can greatly impair vision and function. Both medical and surgical interventions can restore or improve vision problems that occur as a result of disease states of the eye. Low-vision aids, such as special magnifiers and high-intensity lighting that mimics sunlight, can assist in optimizing vision in otherwise uncorrectable ophthalmologic problems.

Mrs. Sora experienced a fall when she first moved to her daughter’s home. Her former home was carpeted, but Beth’s home has hardwood floors. The glare from the polished wood briefly impaired Mrs. Sora’s vision preventing her from seeing her grandson’s toy car, upon which she slipped and fell. Mrs. Sora has a cataract, which makes her less tolerable of glare and likely contributed to her fall.

Hearing

Hearing loss is common among older adults, and some degree of impairment is almost inevitable with advancing age. Among Americans between the ages of 65 and 74, 30% experience hearing impairment, increasing to 47% in adults older than 75 years of age.40

Presbycusis, or the hearing loss of old age, is largely considered multifactorial in etiology. It occurs as a result of aging combined with auditory stressors, trauma, environmental influences, and otologic diseases, as well as genetic factors. It is characterized by a gradual, progressive onset of bilateral and symmetric sensorineural hearing loss of high-frequency tones. The hearing deficit often has both a peripheral and a central component. Speech discrimination, or the ability to distinguish among words that are near-homonyms or distinguish words spoken by several different speakers, often is impaired. Accelerated speech and shouting can increase distortion and further compound the problem. When speaking to hearing-impaired older adults, it is helpful to face them directly so they can observe lip movements and facial expressions. Speech should be slow and direct. Loudness can be irritating. Rephrasing misunderstood messages also can improve understanding of the spoken word. Hearing deficits with age are not always limited to an increased detection threshold, but can include other aspects of hearing, such as sound, comprehension of speech, and noise discrimination, as noted previously.

Mrs. Sora finds it difficult to understand when her grandchildren and daughter speak to her, but she has no problem understanding her son-in-law. This is because the high pitch of child and female voices is more difficult to hear with presbycusis.

Hearing aids can be effective for various levels of hearing loss and may greatly improve the ability to hear and communicate. Cochlear implants may be indicated for people with severe hearing loss not helped by hearing aids.38 Research in the area of hearing restoration by regeneration of cochlear hair cells as well as gene therapy holds promise.42

Cerumen (i.e., earwax) impaction in the external auditory canal also is commonly seen in older adults and can impair hearing. The cerumen glands, which are modified apocrine sweat glands, atrophy and produce drier cerumen. This may be partially responsible for more frequent cerumen impactions in the older adult population.41

Smell and Taste

Olfaction, or the sense of smell, declines with aging, possibly as a result of generalized atrophy of the olfactory bulbs and a moderate loss of olfactory neurons. Smell is a protective mechanism, and people who cannot smell may be at risk for exposure to environmental hazards. For example, people who cannot smell smoke would be at particular risk if a fire broke out.

The sense of taste decreases with aging, but it is believed to be less affected than olfaction. In fact, in many cases what is perceived to be a decline in ability to taste is actually a defect in olfaction. Because taste and smell are necessary for the enjoyment of food flavor, older adults may not enjoy eating as much as in their youth.39 Drugs and disease also may affect taste.38 Alterations in taste and smell, along with other factors such as eating alone, decreased ability to purchase and prepare food, and the high cost of some foods, may account for poor nutritional intake in some older adults. Conversely, the lack of sensory feedback may lead the person to eat more and gain weight. A decline in taste is more pronounced among older adults with Alzheimer disease (AD), presumably because of the neuropathologic changes in the brain.39

Immune Function

A functional immune system is a vital component in surviving microorganism infection and damage caused by other pathogens. Immunosenescence, or age-related changes in the immune system, can pose an increased risk for some infections in older adults.

An example of this would be Mrs. Sora’s outbreak of shingles.

Involution of the thymus gland is complete by approximately 45 to 50 years of age, and although the total number of T cells remains unchanged, there are changes in the function of helper T cells that alter the cellular immune response of older adults. There also is evidence of an increase in various autoantibodies (e.g., rheumatoid factor) as a person ages, increasing the risk of autoimmune disorders.

Extensive studies show that although changes in immunity occur with aging, it is the compounding effects of age-related diseases and external conditions that result in an
overall state of dysfunctional immunity that are responsible for the increased risk and severity of common infections in older adults. Hence, immunosenescence is a predisposing condition, but its contribution to infection risk likely is small until immunity is impaired further as a result of chronic disease, external circumstances, or repeated or chronic infections. This is different from the changes related to immunosuppression resulting from certain conditions such as human immunodeficiency virus infection or immunosuppressive medications that result in unusual opportunistic infections. However, older adults are more susceptible to urinary tract infections, respiratory tract infections, wound infections, and nosocomial infections. The mortality rate from influenza and bronchopneumonia is increased in this population.

Early detection of infections is more difficult in older adults because the typical symptoms, such as fever and elevated white blood cell count, often are absent. A change in mental status or decline in function often is the only presenting sign. It has been reported that frank delirium occurs in 50% of older adults with infections. Thus, infections in older adults may be far advanced at the time of diagnosis.

Gastrointestinal Function

The gastrointestinal tract shows less age-associated change in function than many other organ systems. Although tooth loss is common and approximately 40% to 50% of the older adult population is edentulous, it is not considered part of the normal aging process. Poor dental hygiene with associated caries and periodontal disease is the main reason for the loss. Edentia, or toothlessness, can lead to dietary changes and can be associated with malnutrition. Use of dentures can enhance mastication; however, taste sensation is inhibited. Because of improved dental technology and the fluoridated water supply, more people are able to keep their teeth into their later years. Xerostomia, or dry mouth, also is common, but it is not universal among older adults and typically occurs as a result of decreased salivary secretions. Other causes of dry mouth can include medications, such as anticholinergics and tranquilizers, radiation therapy, and obstructive nasal diseases that induce mouth breathing.

The term *presbyesophagus* has been used to denote changes in esophageal function, such as decreased motility and inadequate relaxation of the lower esophageal sphincter thought to occur with aging. However, in studies that controlled for disease states such as diabetes mellitus and neuropathies, no increase in abnormal motility was observed. In general, the physiologic function of the esophagus appears to remain intact with advancing age.

Atrophy of the gastric mucosa and a decrease in gastric secretions can occur in older adults. Achlorhydria (i.e., decrease in hydrochloric acid secretion) occurs, probably as a result of a loss of parietal cells. Although not universal, achlorhydria is more prevalent among older adults and can cause impaired gastric absorption of substances requiring an acidic environment. *Helicobacter pylori* infestation, which is common in older adults, is thought to play a role in gastric atrophy and subsequent decline in gastric acid secretion.

Atrophic gastritis and decreased secretion of intrinsic factor are more common with aging and can result in a malabsorption of vitamin B₁₂ (cobalamin). Because vitamin B₁₂ is necessary for the maturation of red blood cells, a deficiency can lead to a type of macrocytic anemia called *pernicious anemia*. Vitamin B₁₂ deficiency also can cause neurologic abnormalities such as peripheral neuropathy, ataxia, and even dementia. Treatment traditionally consisted of regular vitamin B₁₂ replacement therapy through injection because the oral form was thought to not be absorbed owing to a lack of intrinsic factor. However, recent research supports the use of high-dose oral cobalamin therapy in increasing serum vitamin B₁₂ levels and improving hematological parameters.

The widespread, and often long-term, use of proton pump inhibitors (PPIs) for acid-related disorders in older adults has brought attention to potential adverse effects. Overuse or misuse of PPI therapy may interfere with vitamin B₁₂ absorption and contribute to polypharmacy and drug interactions. Additional potential adverse effects of PPI use include an increased risk of *Clostridium difficile*–associated diarrhea and community-acquired pneumonia. The usually acidic environment of the stomach acts as a defense against ingested bacteria. The subsequent increase in gastric pH with the use of PPIs facilitates survival of pathogens that would have succumbed to a more acidic environment.

The small intestine shows some age-related morphologic changes, such as mucosal atrophy. However, absorption of most nutrients and other functions appear to remain intact. Absorption of calcium, however, decreases with aging and may reflect decreased intestinal absorption along with other factors, such as reduced intake of vitamin D, decreased formation of vitamin D₃ by the skin because of reduced sun exposure, and decreased activation of vitamin D₃ by the liver and kidney.

Diverticula of the colon are common among older adults, with more than 50% of people older than 80 years having diverticular disease. The high incidence appears to result mainly from a low-fiber diet. Constipation, or infrequent passage of hard stool, is another frequently occurring phenomenon. It often is attributed to immobility and decreased physical activity, a low-fiber diet, decreased fluid intake, and medications; malignancies and other disease states also can be responsible. Complications of constipation can include fecal impaction or obstruction, megacolon, rectal prolapse, hemorrhoids, and laxative abuse.

Renal Function

Although age-related anatomic and physiologic changes occur, the aging kidney remains capable of maintaining fluid and electrolyte balance remarkably well. Aging changes result in a decreased reserve capacity, which may alter the kidney’s ability to maintain homeostasis in the face of illnesses or stressors. Overall, there is a general decline in kidney mass with aging, predominantly in the renal cortex. The number of functional glomeruli decreases by 30% with an increased percentage of sclerotic or abnormal glomeruli.

Numerous cross-sectional and longitudinal studies have documented a steady, age-related decline in total renal blood
flow of approximately 10% per decade after 20 years of age, so that the renal blood flow of an 80-year-old person averages approximately 300 mL/minute, compared with 600 mL/minute in a younger adult. The major decline in blood flow occurs in the cortical area of the kidney, causing a progressive, age-related decrease in the GFR. Serum creatinine, a by-product of muscle metabolism, often is used as a measure of GFR. The decline in GFR that occurs with aging is not accompanied by an equivalent increase in serum creatinine levels because the production of creatinine is reduced as muscle mass declines with age.50 Serum creatinine levels often are used as an index of kidney function when prescribing and calculating drug doses for medications that are eliminated through the kidneys. This has important implications for older adults. If not carefully addressed, improper drug dosing can lead to an excess accumulation of circulating drugs and result in toxicity. A formula that adjusts for age-related changes in serum creatinine for people 40 through 80 years of age is available.

Renal tubular function declines with advancing age, and the ability to concentrate and dilute urine in response to fluid and electrolyte impairments is diminished. The aging kidney’s ability to conserve sodium in response to sodium depletion is impaired and can result in hypotension and dehydration. A decreased ability to concentrate urine, an age-related decrease in responsiveness to antidiuretic hormone, and an impaired thirst mechanism may account for the older adult’s greater predisposition to dehydration during periods of stress and illness. Older adults also are more prone to hyperkalemia and hypokalemia when stressed compared to younger people. An elevated serum potassium may result from a decreased GFR, lower renin and aldosterone levels, and changes in tubular function. Low potassium levels, on the other hand, are more commonly caused by gastrointestinal disorders or diuretic use. Neither is the result of aging.52

Genitourinary Function

Both men and women undergo changes in genitourinary function as a result of the aging process. There are changes in bladder structure and function, decreases in steroid sex hormones, and changes in genital structures.

Changes in the bladder structure that occur because of the aging process can result in a decline in function. Overall, the smooth muscle and supportive elastic tissue are replaced with fibrous connective tissue. This can cause incomplete bladder emptying and a diminished force of urine stream. Bladder capacity also decreases with age, whereas the frequency of urination increases. As elastic tissue and muscles weaken, stress incontinence becomes more prevalent.

In aging women, atrophy of perineal structures can cause the urethral meatus to recede along the vaginal wall. Atrophy of other pelvic organs occurs in the aging woman because of diminished estrogen production after menopause: vaginal secretions diminish; the vaginal lining is thinner, drier, less elastic, and more easily traumatized; and normal flora are altered. These changes can result in vaginal infections, pruritus, and painful intercourse.53

In aging men, benign prostatic hyperplasia (BPH) is very common. The incidence progressively increases to approximately 90% of men by 80 years of age. The condition often is asymptomatic until approximately 50 years of age. Thereafter, the incidence and severity of symptoms increase with age. BPH can cause obstructive symptoms such as urinary hesitancy, diminished force of stream, retention, and postvoid dribbling. It also can cause irritative symptoms such as frequency, nocturia, urgency, and even urge incontinence.54

Serum testosterone levels are known to decline as men age, although the definition of and treatment for hypogonadism remain somewhat controversial. Symptoms associated with androgen deficiency in the aging man can include diminished muscle strength, stamina, and energy; loss of muscle mass; low libido (with or without erectile dysfunction); irritable mood; osteoporosis; and testicular atrophy. Although several groups have developed some guidelines for androgen replacement therapy for older men, there is a general lack of consensus on whether to treat androgen deficiency.55

Sexual activity remains possible into late life for men and women. In general, the duration and intensity of the sexual response cycle are diminished in both sexes. Women take longer to experience the physiologic changes of vaginal expansion and lubrication during the excitement phase. Penile erection in aging men takes longer to develop because of changes in neural innervation and vascular supply. Social factors affecting sexual behavior include the desire to remain sexually active, access to a sexually functioning partner, and availability of a conducive environment.56,57

IN SUMMARY

There is a general decline in the structure and function of the body with advancing age, resulting in a decreased reserve capacity of the various organ systems, including the integumentary, musculoskeletal, cardiorespiratory, nervous, sensory, immune, gastrointestinal, and genitourinary systems (see Fig. 3.2). This results in a reduction of homeostatic capabilities, making the older adult more vulnerable to stressors such as illness, trauma, surgery, medication administration, and environmental changes.

FUNCTIONAL PROBLEMS ASSOCIATED WITH AGING

After completing this section of the chapter, you should be able to meet the following objectives:

- State four risk factors for falls in older adults.
- List five symptoms of depression in older adults.
- Name a tool that can be used for assessing cognitive function.
- State the difference between delirium and dementia.
Although aging is not synonymous with disease, the aging process does lend itself to an increased incidence of illness. As chronic age increases, so does the probability of having multiple chronic diseases. The vast majority of older adults have at least one chronic condition, and most have more than one. The extent of these problems is described in Table 3.1. Older adults are more likely to experience a decline in overall health and function because of the increased incidence of chronic illness that occurs with advancing age. Because aging also brings with it a decreased ability to maintain homeostasis, illnesses often manifest in an atypical manner. For example, myocardial infarction may occur without chest pain or other presenting symptoms. Sepsis without fever is common, and pneumonia may present with acute confusion but lack the prodromal symptom of cough.

In addition to chronic illnesses, older adults suffer disproportionately from functional disabilities, or the inability to perform the necessary ADLs. It is most likely that the decrements in health that can accompany the aging process are responsible for these functional disabilities. Among the more common functional problems of the older adult are urinary incontinence, instability and falls, sensory impairment, and depression and cognitive impairment.

**Functional Assessment**

Evaluation of the older adult’s functional abilities is a key component of gerontologic health care. Medical diagnoses alone are incomplete without an assessment of function. Two older adults with similar medical diagnoses of arthritis, hypertension, and osteoporosis, for example, can be at opposite ends of the spectrum of functional abilities.

Assessing functional status can be done in many different ways, using a variety of methods. Measures of function should attempt systematically and objectively to evaluate the level at which an individual is functioning in a variety of areas, including biologic, psychological, and social health.

Selection of a screening tool to measure function depends on the purpose of data collection, the individual or target population to be assessed, availability and applicability of the instruments, reliability and validity of the screening tools, and the setting or environment. An issue that arises when assessing function is the question of capability versus performance. For example, an older adult may be able to bathe without supervision; however, the long-term care facility where the person resides may discourage it for safety reasons. Among the more commonly used assessment tools are those that measure the ability to perform ADLs and the patient’s cognitive function.

When evaluating levels of function, determination of the older adult’s ability to perform ADLs and instrumental ADLs (IADLs) should be included. ADLs are basic self-care tasks, such as bathing, dressing, grooming, ambulating, transferring (e.g., from a chair to bed), feeding, and communicating. IADLs are more complex tasks that are necessary to function in society, such as writing, reading, cooking, cleaning, shopping, laundrying, climbing stairs, using the telephone, managing money, managing medications, and using transportation. The IADL tasks indirectly examine cognitive abilities as well because they require a certain level of cognitive skill to complete.

Several tools are available for measuring functional status. One of the more commonly used tools is the Index of Activities of Daily Living. Developed by Katz in 1963 and revised in 1970, it summarizes performance in six functions:

- Bathing
- Dressing
- Toileting
- Transferring
- Continence
- Feeding

It is used as an assessment tool to determine the need for care and the appropriateness of treatment and as a teaching aid in rehabilitation settings. Through questioning and observation, the rater forms a mental picture of the older adult’s functional status as it existed during a 2-week period preceding the evaluation, using the most dependent degree of performance. Numerous studies using the Katz Index tool show significant validity and reliability. The advantage of the tool is that it is easy to administer and provides a “snapshot” of the older adult’s level of physical functioning. The disadvantage is that it does not include IADL categories that are of equal importance, especially for older adults living in the community. The Lawton Instrumental Activities of Daily Living (IADL) Scale assesses skills necessary for independent living. It reflects how the person is functioning currently and can be used to identify new disabilities and prompt further assessment of vulnerable older adults. Eight domains of function are measured:

- Ability to use the telephone
- Shopping
- Food preparation
- Housekeeping
- Laundry
- Mode of transportation
- Responsibility for own medication
- Ability to handle finances
Urinary Incontinence

Urinary incontinence, or involuntary loss of urine, plagues over 30% of community-living people older than 60 years of age and 60% to 80% of residents in long-term care facilities. These estimates may be low because people often fail to report symptoms of urinary incontinence, perhaps owing to the attached social stigma. Health care professionals often neglect to elicit such information as well.

Incontinence is an expensive problem. A conservative estimate of cost for direct care of adults with incontinence is over $19.5 billion annually. Urinary incontinence can have deleterious consequences, such as social isolation and embarrassment, depression and dependency, rashes and pressure sores, and financial hardship. Although urinary incontinence is a common disorder, it is not considered a normal aspect of aging. Adults with urinary incontinence can be successfully treated and even cured.

Etiology and Pathogenesis

Changes in the micturition cycle that accompany the aging process make the older adult prone to urinary incontinence. A decrease in bladder capacity, in bladder and sphincter tone, and in the ability to inhibit detrusor (i.e., bladder muscle) contractions, combined with the nervous system’s increased variability in interpreting bladder signals, can cause incontinence. Impaired mobility and a slower reaction time also can aggravate incontinence.

The causes of incontinence can be divided into two categories—transient and chronic. Of particular importance is the role of pharmaceuticals as a cause of transient urinary incontinence. Numerous medications, such as long-acting sedatives and hypnotics, psychotropics, and diuretics, can induce incontinence. Rectal distension from fecal impaction may stimulate involuntary bladder contractions. Acute cystitis or polyuria caused by hyperglycemia or hypercalcemia can precipitate incontinence.

Treatment of transient urinary incontinence is aimed at ameliorating or relieving the cause on the assumption that the incontinence will resolve.

Chronic, or established, urinary incontinence occurs as a failure of the bladder to store urine or a failure to empty urine. Failure to store urine can occur as a result of detrusor muscle overactivity with inappropriate bladder contractions (i.e., urge incontinence). There is an inability to delay voiding after the sensation of bladder fullness is perceived. Urge incontinence is typically characterized by large-volume leakage episodes occurring at various times of day. Urethral incompetence (i.e., stress incontinence) also causes a bladder storage problem. The bladder pressure overcomes the resistance of the urethra and results in urine leakage. Stress incontinence causes an involuntary loss of small amounts of urine with activities that increase intra-abdominal pressure, such as coughing, sneezing, laughing, or exercising.

Failure of the bladder to empty urine can occur because of detrusor instability, resulting in urine retention and overflow incontinence. Also called neurogenic incontinence, this type of incontinence can be seen with neurologic damage from conditions such as diabetes mellitus and spinal cord injury. Outlet obstruction, as with prostate enlargement and urethral stricture, also can cause urinary retention with overflow incontinence. Functional incontinence, or urine leakage due to toileting problems, occurs because cognitive, physical, or environmental barriers impair appropriate use of the toilet.

Treatment

After a specific diagnosis of urinary incontinence is established, treatment is aimed at correcting or ameliorating the problem. Probably the most effective interventions for older adults with incontinence are behavioral techniques. These strategies involve educating the person and providing reinforcement for effort and progress. Techniques include bladder training, timed voiding or habit training, prompted voiding, pelvic floor muscle (i.e., Kegel) exercises, and dietary modifications.

Biofeedback, a training technique to teach pelvic floor muscle exercises, uses computerized instruments to relay information to individuals about their physiologic functions. Biofeedback can be helpful when used with other behavioral treatment techniques. Use of pads or other absorbent products should be seen as a temporary measure and not as a cure. Numerous types of products are available to meet many different consumer needs.

Pharmacologic intervention may be helpful for some people. Oral estrogen replacement therapy in postmenopausal women is no longer recommended as a treatment approach in light of information about the cardiovascular side effects and increased cancer risks that estrogen can pose. However, topical estrogen in low doses is effective in decreasing urge incontinence and, to a lesser extent, stress incontinence. Antimuscarinic drugs (e.g., oxybutynin, tolterodine, darifenacin) are approved for use in overactive bladder and urge incontinence. Their anticholinergic side effects such as dry mouth, constipation, and potential for central nervous system side effects make it necessary to weigh the risks against the benefits, which are limited at best. Duloxetine, a serotonin and norepinephrine reuptake inhibitor, has been studied for the treatment of stress incontinence. It increases α-adrenergic tone to the urethra, but it has not been approved for this indication in the United States.

Surgical intervention may help to relieve urinary incontinence symptoms in appropriate patients. Bladder neck suspension may assist with stress incontinence unresolved by other interventions, and prostatectomy may be appropriate for men with overflow incontinence due to an enlarged prostate. Minimally invasive surgical options include midurethral slings and implantation of an artificial urinary sphincter. Some older adults may have medical conditions that preclude surgery.

Other treatments for stress incontinence include insertable pessary devices that support pelvic organ prolapse and urethral bulking agents such as silicone or collagen. Overactive bladder with urgency can be treated with a sacral neuromodulation device or off-label botulinum toxin A bladder injections. Intermittent self-catheterization is used for some types of overflow incontinence.
Instability and Falls

Unstable gait and falls are a common source of concern for the older adult population. The literature reveals that 30% of community-dwelling people older than 65 years of age and 50% of nursing home residents fall each year. Most falls do not result in serious injury, but the potential for serious complications and even death is real. Accidents are the fifth leading cause of death among older adults, with falls ranking first in this category. Falls among older adults were estimated to cost the US health care system over $19 billion dollars in 2000. That figure is expected to increase to $54.9 billion by the year 2020.68

The way in which a person falls can often determine the type of injury that occurs. Wrist fractures are common and frequently sustained from forward or backward falls onto an outstretched hand. Hip fractures can result from a sideways fall and are one of the most feared complications from a fall. Hip fractures predominate in the 75 years and older age group. Significant morbidity ensues from a hip fracture. The literature varies, but as much as 50% of older adults who sustain a hip fracture never regain their ability to walk independently, and up to 20% die in the year after a hip fracture.62 The problem of falls in the older adult population is an issue of high incidence combined with a high potential for injury, owing to the high prevalence of medical problems along with physiologic changes that occur with advancing age. In addition, recovery from a fall-related injury can be lengthy and result in deconditioning, weakness, and abnormality of gait, further potentiating the risk of subsequent falls.62 An older adult’s activity may be restricted because of fear on the older adult’s or caregiver’s part about possible falling. These anxieties may lead to unnecessary restrictions in independence and mobility and commonly are mentioned as a reason for institutionalization.69

Risk Factors

Although some falls have a single, obvious cause, such as a slip on a wet or icy surface, most are the result of several factors. Risk factors that predispose to falling include a combination of age-related biopsychosocial changes, chronic illnesses, and situational and environmental hazards. Table 3.2 summarizes the possible causes of falls.

Gait and stability require the integration of information from the special senses, the nervous system, and the musculoskeletal system. Changes in gait and posture that occur in healthy older adults also contribute to the problem of falls. The older adult’s stride shortens; the elbows, trunk, and knees become more flexed; toe and heel lift decrease while walking; and sway while standing increases. Muscle strength and postural control of balance decrease, proprioception input diminishes, and righting reflexes slow.6,57–72 Because the central nervous system integrates sensory input and sends signals to the effector components of the musculoskeletal system, any alteration in neural function can predispose to falls. For this reason, falls have been associated with strokes, Parkinson disease, and normal-pressure hydrocephalus. Similarly, diseases or disabilities that affect the musculoskeletal system, such as arthritis, muscle weakness, or foot deformities, are associated with an increase in the incidence of falls.6,73–74

Age- and disease-related alterations in vision and hearing can impair sensory input, increasing the risk for falls.75,76 Vestibular system alterations such as benign positional vertigo or Ménière disease cause balance problems that can result in falls. Input from the cardiovascular and respiratory systems influences function and ambulation. Syncope, a type of dizziness, is a transient global cerebral hypoperfusion stemming from cardiovascular symptoms. Syncope occurs fairly rapidly and usually results in falling. Syncope is common among

older adults. \(^3\) Cognitive impairments such as dementia have been associated with an increased risk of falling, most likely because of impaired judgment and problem-solving abilities. \(^7\)

Medications are an important and potentially correctable cause of instability and falls. Central-acting medications, such as sedatives and hypnotics, have been associated with an increase in the risk of falling and injury. Diuretics can cause volume depletion, electrolyte disturbances, and fatigue, predisposing to falls. Antihypertensive drugs can cause fatigue, orthostatic hypotension, and impaired alertness, contributing to the risk of falls.\(^8,\)\(^7\)

Environmental hazards play a significant role in falling. Most falls occur in the home and often involve objects that are tripped over, such as cords, scatter rugs, and small items left on the floor. Poor lighting, ill-fitting shoes, surfaces with glare, and improper use of ambulatory devices such as canes or walkers also contribute to the problem.\(^7\)\(^,\)\(^2\)

Mrs. Sora’s second fall occurred at night when experiencing urinary urgency. She was rushing to the bathroom in dim lighting and bare feet and slipped on the bath mat.

**Preventing Falls**

Preventing falls is the key to controlling the potential complications that can result. Because multiple factors usually contribute to falling, the aim of the clinical evaluation is to identify risk factors that can be modified. Assessment of sensory, neurologic, and musculoskeletal systems; direct observation of gait and balance; and a careful medication inventory can help identify possible causes. Preventive measures can include a variety of interventions, such as surgery for cataracts or cerumen removal for hearing impairment related to excessive earwax accumulation.\(^8\) Other interventions may include podiatric care, discontinuation or alteration of the medication regimen, exercise programs, physical therapy, and appropriate adaptive devices.\(^7\) The home also should be assessed by an appropriate health care professional (e.g., occupational therapist) and recommendations made regarding modifications to promote safety. Simple changes such as removing scatter rugs, improving the lighting, and installing grab bars in the bathtub can help prevent falling.\(^7\)

Use of specially designed external hip protector pads in high-risk older adults has demonstrated a dramatic reduction in hip fractures occurring after a fall. The impacting force and energy caused by the fall are weakened and diverted away from the greater trochanteric region by use of the pad. Greatest benefit is seen in the older adult population residing in long-term care facilities. Compliance is somewhat problematic, however, because people may be reluctant to wear the pads.\(^7\)\(^,\)\(^4\)\(^4\)\(^,\)\(^7\) Vitamin D supplementation has also shown promising results and may have an independent role in the prevention of falls. Use of vitamin D is credited with improvement in functional strength and dynamic muscle performance, thereby reducing fall risk.\(^7\)\(^8\) A recent examination of systematic reviews and meta-analyses of vitamin D supplementation for prevention of hip fractures revealed a beneficial effect to high-dose vitamin D supplementation combined with calcium.\(^7\)

**Sensory Impairment**

Although sensory impairments are not imminently life threatening, their impact on health can be substantial. Hearing impairment is associated with decreased quality of life, depression, isolation, and dementia. Visual impairment is related to increased risk of falls, hip fractures, physical disability, and depression. Nursing home residents with visual impairment are more likely to require assistance with ADLs and can be at risk for falls and hip fractures. Visual impairment also appears to increase mortality rates.\(^7\)\(^9\)\(^,\)\(^4\)\(^1\)\(^7\)\(^7\)\(^9\)

Sensory impairment results not only from deficits in peripheral sensory structures but from the central processing of sensory information. The older person’s difficulty in processing multisensory information is seen most strikingly when there is a rapid fluctuation in the nature of the information that is received from the environment.\(^7\)

Lack of sensory information can predispose to psychological symptoms. Charles Bonnet syndrome is an organic disorder occurring in older adults that is characterized by complex visual hallucinations. It is associated with ocular disease and, strictly speaking, is seen in older adults with preserved intellectual functions.\(^8\)\(^0\)\(^3\)\(^1\) Those who obtain insight into the problem generally only need reassurance that their hallucinations do not represent mental illness. For those who have limited insight and are distressed by the symptom, antipsychotics may afford some relief.\(^8\) Both auditory and visual impairments can have important psychological effects in association with dementia. Delusions have long been associated with hearing impairment.\(^8\) However, a recent systematic review of cohort studies that focused on late-onset psychosis determined that visual impairment was a greater risk factor.\(^8\)

**Depression**

Depression is a significant health problem affecting the older adult population. It is the most common geriatric psychiatric disorder. Estimates of the prevalence of depression in older adults vary widely. However, there is a consensus that the size of the problem is underestimated owing to misdiagnosis and mistreatment. Up to 25% of community-dwelling older adults are thought to have depressive symptoms. The estimate drops to approximately 1% to 2% when diagnosis is restricted to major depression.\(^8\)\(^4\)\(^8\)\(^5\) Depressive symptoms are even more common in nursing home residents.\(^8\)\(^5\)\(^8\)

**Clinical Manifestations and Diagnosis**

The term *depression* is used to describe a symptom, syndrome, or disease. As listed in the fourth edition of the American Psychiatric Association’s *Diagnostic and Statistical Manual of Mental Disorders (DSM-IV-TR)*, the criteria for the diagnosis and treatment of a major depression include at least five of the following symptoms during the same 2-week period,
with at least one of the symptoms being depressed mood or anhedonia (i.e., loss of interest or pleasure):

- Depressed or irritable mood
- Loss of interest or pleasure in usual activities
- Appetite and weight changes
- Sleep disturbance
- Psychomotor agitation or retardation
- Fatigue and loss of energy
- Feelings of worthlessness, self-reproach, or excessive guilt
- Diminished ability to think or concentrate
- Suicidal ideation, plan, or attempt

Depressive symptomatology can be incorrectly attributed to the aging process, making recognition and diagnosis difficult. Depressed mood, the signature symptom of depression, may be less prominent in the older adult, and more somatic complaints and increased anxiety are reported, confusing the diagnosis. Symptoms of cognitive impairment can be seen in the depressed older adult. Although a thorough investigation is necessary to discern whether the symptoms are a result of depression versus dementia, evidence now shows that depression can be a prodromal symptom of dementia.

Physical illnesses can complicate the diagnosis as well. Depression can be a symptom of a medical condition, such as pancreatic cancer, hypothyroidism or hyperthyroidism, pneumonia and other infections, congestive heart failure, dementia, and stroke. In fact, major depression is a common consequence of stroke and occurs in about one third of all people with ischemic stroke. Medications such as sedatives, hypnotics, steroids, antihypertensives, and analgesics also can induce a depressive state. Numerous confounding social problems, such as bereavement, loss of job or income, and loss of social support, can contribute to the diagnosis.

Mrs. Sora’s daughter expresses concern about her mother’s emotional state. Since her move, she has been withdrawn and does not participate in activities she used to enjoy such as crocheting. She has not expressed any interest in visiting the senior center as a way to socialize, and she does not eat unless offered food at meal times. Beth can hear her mother up at night watching television, seemingly unable to fall asleep. Although she has had a complete physical examination with lab work, Mrs. Sora still complains of “just not feeling right.”

The course of depression in older adults is similar to that in younger people. As many as 40% experience recurrences. Suicide rates are highest among older adults. There is a linear increase in suicide with age, most notably among white men older than 65 years of age. The exact reasons are unclear. Predictors include depression, physical illness and disability, loss of a spouse, and social isolation.

Because diagnosis of depression can be difficult, use of a screening tool may help to measure affective functioning objectively. The Geriatric Depression Scale, an instrument of known reliability and validity, was developed to measure depression specifically in the noninstitutionalized older adult population. The 30-item dichotomous scale elicits information on topics relevant to symptoms of depression among older adults, such as memory loss and anxiety. Many other screening tools, each with its own advantages and disadvantages, exist to evaluate the older adult’s level of psychological functioning, in its entirety or as specific, separate components of function.

Mrs. Sora’s Geriatric Depression Scale score indicated depression. Bereavement over loss of her spouse and social isolation were two big risk factors.

**Treatment**

Treatment goals for older adults with depression are to decrease the symptoms of depression, improve the quality of life, reduce the risk of recurrences, improve health status, decrease health care costs, and decrease mortality.

**Pharmacologic Treatment.** Pharmacotherapy (i.e., use of antidepressants) is an effective treatment approach for the depressed older adult. The selection of a particular medication depends on a variety of factors, such as a prior positive or negative response, history of first-degree relatives responding to medication, concurrent medical illnesses that may interfere with medication use, concomitant use of nonpsychotropic medications that may alter the metabolism or increase the side effect profile, likelihood of adherence, patient preference, and cost. Selective serotonin reuptake inhibitors (SSRIs), a class of antidepressants (e.g., sertraline, citalopram, escitalopram), provide high specificity by blocking or slowing serotonin reuptake without the antagonism of neurotransmitter receptors or direct cardiac effects. Because of this, they are an attractive first choice for pharmacotherapy. Dosing is usually once per day, creating ease of administration. They also are less lethal in overdose than other types of antidepressants, such as the tri cyclics, an important consideration because of the high suicide rate among older adults. The anticholinergic and cardiovascular side effects that can be problematic with tricyclic antidepressants (e.g., nortriptyline, desipramine, amitriptyline) are minimal with SSRIs. Atypical antidepressants (e.g., bupropion, mirtazapine) and serotonin and noradrenaline reuptake inhibitors (SNRIs) (e.g., venlafaxine, duloxetine) have begun to have a role in late-life depression. Similar in efficacy to SSRIs, clinicians may select one of these drugs for both its antidepressant and side effect properties. For example, mirtazapine is an antidepressant with associated sedation and increased appetite; it would be appropriate for a depressed elder with poor appetite and insomnia. Regardless of the classification, psychotropic medications should be given in low doses initially and gradually titrated according to response and side effects. Response to antidepressants usually requires 4 to 6 weeks at therapeutic dose levels. For a single episode of major depression, drug
therapy usually should continue for a minimum of 6 months to 1 year at the same dose that achieved remission, and 2 to 5 years for recurrent depression, to prevent relapse.98-101

**Electroconvulsive Therapy.** Electroconvulsive therapy (ECT) may be the treatment of choice for older adults with severe, pharmacologically resistant major depressive episodes. Studies indicate that people older than 60 years of age are the largest group of patients who receive ECT. Despite the negative publicity that has been associated with ECT, the evidence for its efficacy in the treatment of depression is strong. Unfortunately, relapse after ECT is common, and alternative treatment strategies, including maintenance ECT or maintenance antidepressants after ECT, are being used.102-104

**Psychotherapy.** “Talking therapy,” such as supportive counseling or psychotherapy, is considered to be an important part of the treatment regimen, alone or in combination with pharmacotherapy or ECT. Alterations in life roles, lack of social support, and chronic medical illnesses are just a few examples of life event changes that may require psychosocial support and new coping skills. Counseling in the older adult population requires special considerations. People with significant vision, hearing, or cognitive impairments may require special approaches. Many elderly people do not see themselves as depressed and reject referrals to mental health professionals. Special efforts are needed to engage these people in treatment. Cognitive behavioral therapy teaches older adults how to identify and challenge distressing thoughts and then to reframe how they perceive or react to a situation. Some older adults may prefer this type of therapy as it is briefer and time limited as compared to other therapies such as psychoanalysis.100,105,106 Although depression can impose great risks for older adults, it is thought to be the most treatable psychiatric disorder in late life and therefore warrants aggressive case finding and intervention.

**Dementia**

Dementia is a complex and devastating problem that is a major cause of functional disability, dependence, and mortality in the older adult population. Estimates vary, but indicate that the prevalence of dementia in the United States is 5% to 10% in older adults, with the rate increasing with advancing age.107

Although there can be a decline in intellectual function with aging, dementia, formerly called senility, is not a normal aging process. Dementia is a syndrome of acquired, persistent impairment in several domains of intellectual function, including memory, language, visuospatial ability, and cognition (i.e., abstraction, calculation, judgment, and problem solving). The cognitive changes are sufficient to impair social and occupational function. Mood disturbances and changes in personality and behavior often accompany the intellectual deterioration.57

**Etiology and Pathogenesis**

Dementia or cognitive dysfunction can result from a wide variety of conditions, including degenerative, vascular, neoplastic, demyelinating, infectious, inflammatory, toxic, metabolic, and psychiatric disorders. Up to 70% of older adults with dementia (4.5 million Americans and 15 million people worldwide) are thought to have AD, a chronic, progressive neurologic disorder of unknown cause. Two microscopic changes occur in the brains of people with AD—senile plaques that develop between neurons, and neurofibrillary tangles that develop within neurons. Researchers have speculated that inflammation around plaques destroys neighboring neurons. Involvement of cholinergic neurons causes levels of acetylcholine in synapses to decline. Levels of acetylcholinesterase also drop, perhaps to compensate for the loss of acetylcholine.108-110 Vascular dementia is the second most common disorder, and risk factors include ischemic stroke, hemorrhagic stroke, hypertension, hyperlipidemia, heart disease, tobacco use, and diabetes mellitus.111-113

**Diagnosis**

Currently there are no specific diagnostic tests to determine the presence of AD. The diagnosis is made by excluding other possible causes of the dementia symptoms. The only confirmatory test for AD is examination of brain tissue on autopsy. More recently, use of positron emission tomography (PET) scans of the brain using a newer imaging molecule has proved to be of value in diagnosis. Research has shown that it can help differentiate the diagnosis by determining regional cerebral patterns of amyloid plaques and tau neurofibrillary tangles.114

A commonly used measure of cognitive function is the Mini-Mental State Examination (MMSE), developed by Folstein and colleagues in 1975.115 This tool provides a brief, objective measure of cognitive functioning and has been widely used. The MMSE, which can be administered in 5 to 10 minutes, consists of a variety of questions that cover memory, orientation, attention, and constructional abilities. The test has been studied and found to fulfill its original goal of providing a brief screening tool that quantifies cognitive impairments and documents cognitive changes over time. However, it has been cautioned that this examination should not be used by itself as a diagnostic tool to identify dementia.116

**Treatment**

**Pharmacologic Treatment.** Several medications have become available over the past decade to help halt further cognitive decline in AD. At present, three drugs (donepezil, rivastigmine, and galantamine) are available in the therapeutic category of cognitive-enhancing agents. All three medications are acetylcholinesterase inhibitors whose action elevates acetylcholine concentrations in the cerebral cortex by slowing degradation of acetylcholine released by still-intact neurons. The medications are similar in efficacy but vary in their dosing and side effect profiles. While all three have gastrointestinal side effects (e.g., nausea, loose stool), donepezil seems to have the mildest symptoms; it also has the benefit of once daily dosing. Donepezil is the only agent approved for mild, moderate, and severe stages of AD. Rivastigmine is available as a 24-hour transdermal patch. Although there still is no cure for dementia, acetylcholinesterase inhibitors
are considered efficacious as antidementia drugs on the basis of improvements seen on standardized cognitive tests as well as a slower decline in loss of function due to the disease process. There is research to suggest that there is an advantage to starting a cholinesterase inhibitor as early as possible after the diagnosis of mild AD.\textsuperscript{117,118} There is no strong evidence to suggest that the cognitive-enhancing drugs are beneficial in people with vascular dementia. However, it would be appropriate to use them in a case of mixed AD and vascular dementia.\textsuperscript{118}

Memantine, a moderate-affinity, uncompetitive N-methyl-D-aspartate (NMDA) receptor antagonist, is a newer agent that has consistently demonstrated safe and efficacious use in dementia. Glutamate is a neurotransmitter that potentially overexcites NMDA receptors, and excessive release of glutamate is believed to contribute to the neurodegeneration associated with AD. Memantine has known clinical efficacy in treating patients with moderate to severe AD. It has not proven to be efficacious in the treatment of mild AD.\textsuperscript{119} The slowing of cognitive and functional decline offered by the cholinesterase inhibitors and memantine decreases caregiver burden and prolongs the period an older adult with AD can remain in the community. There has also been interest in other neuroprotective drugs that may delay the onset or progression of AD. Nonsteroidal anti-inflammatory drugs (NSAIDs) are thought to decrease the inflammatory response to inflammatory mediators released from injured or degenerating nerve cells, although study results are somewhat inconclusive. Because of these general concerns about lack of efficacy, combined with potential side effects (e.g., cardiac toxicity, bleeding), NSAIDs are not considered a standard treatment for AD.\textsuperscript{120,121} Cholesterol promotes beta-amyloid production. Lipid-lowering agents, such as the statin drugs, decrease cholesterol and reduce inflammation. However, thus far, studies have been disappointing in their outcomes in that they have shown no protective effect against cognitive decline.\textsuperscript{120,121}

Dietary and nutritional supplements are thought to have beneficial effects in either the prevention of AD or slowing the progression of the disease. Vitamin E, an antioxidant, may play a role in AD prevention. Vitamin E, a fat-soluble vitamin, interacts with cell membranes, traps free radicals, and may interrupt chain reactions that damage cells. Although earlier studies were promising, more recent investigation of the long-term use of vitamin E did not demonstrate cognitive benefits among those with mild cognitive impairment or AD. There needs to be more research done regarding vitamin E’s role in the primary prevention of dementia.\textsuperscript{117,120,121} Ginkgo biloba, another antioxidant, has unclear clinical benefits. A Cochrane review determined that the evidence supporting G. biloba was not consistent or reliable.\textsuperscript{122} Elevated plasma homocysteine concentrations have been linked as a vascular risk factor in the development of dementia and can be lowered by folic acid supplementation. A recent systematic review that studied the use of B vitamins in the prevention and treatment of AD and dementia determined that there was insufficient evidence to support the theory that increased dietary intake or supplementation of folic acid impacted cognitive decline.\textsuperscript{123}

**Nonpharmacologic Treatment.** Studies have also shown that certain mental exercises can offset some of the expected cognitive changes that can occur with aging. Cognitive training utilizes strategies to enhance cognitive functions such as memory, attention, or problem solving. The goal is to maintain or improve cognitive function and compensate for deficits. This can be accomplished through both memory training approaches and computer-assisted cognitive interventions.\textsuperscript{124} Likewise, physical exercise, such as aerobics or weight training, may have the potential for delaying functional decline in people with AD and may even help to delay the onset of dementing disorders.\textsuperscript{125-127}

In more advanced cases of dementia, ensuring that the individual’s physical needs, such as hygiene, bowel and bladder elimination, safety, and nutrition, are met can help prevent catastrophic reactions. Providing a consistent routine in familiar surroundings also helps to alleviate stress. Matching the cognitive needs of the older adult by avoiding understimulation and overstimulation often helps in preventing behavior problems. The work of Hall has shown positive results in the care of older adults with AD.\textsuperscript{128} Hall’s conceptual model, progressively lowered stress threshold (PLST), proposes that the demented person’s ability to tolerate any type of stress progressively declines as the disease advances. Interventions for the older adult with dementia therefore center on eliminating and avoiding stressors as a way to prevent dysfunctional behaviors. These stressors include fatigue, change of routine, excessive demands, overwhelming stimuli, and physical stressors. Hall’s work with the PLST model has shown that people with dementia tend to awaken less at night, use less sedatives and hypnotics, eat better, socialize more, function at a higher level, and experience fewer episodes of anxiety, agitation, and other dysfunctional behaviors. Further work has shown that family caregivers trained using the PLST model improved their abilities to provide care to loved ones with dementia and lowered their own stress levels.\textsuperscript{128,129}

Management of older adults with AD and other dementias usually involves assuming increasing responsibility for and supplying increasing care to the demented person as the illness renders them incapable. Impaired judgment and cognition can prevent the older adult from making reasonable decisions and choices and eventually threatens their overall well-being. Family members often assume the monumental task of caring for older adults with dementia until the burden becomes too great, at which time many older adults may be relocated to long-term care facilities.

**Delirium**

It is important to differentiate dementia from delirium, also referred to as acute confusional state. Delirium can occur in any age group. However, older adults, especially demented older adults, are far more likely to become delirious. The onset of delirium in the demented person may be mistaken as an exacerbation of the dementia and consequently not treated.\textsuperscript{130,131} Up to 70% of cases of delirium go undetected.\textsuperscript{132}
Delirium is an acute disorder developing over a period of hours to days and is seen frequently in hospitalized older adults. Prevalence rates range from 14% to 56% of hospitalized older adults, up to 62% of older adults after surgery, and up to 87% of those in intensive care. Delirium is defined by the DSM-IV-TR as an organic mental syndrome featuring a global cognitive impairment, disturbances of attention, reduced level of consciousness, increased or decreased psychomotor activity, and a disorganized sleep–wake cycle. The severity of the symptoms tends to fluctuate unpredictably but often is more pronounced in the late afternoon or evening. The exact reason why delirium occurs is unclear. It is speculated that the mechanism involves the reversible impairment of multiple neurotransmitters. Other possible contributing factors include vision and hearing impairments, psychological stress, and diseases of other organ systems. Delirium has a high mortality rate, ranging between 10% and 76%. Delirium is associated with increased length of hospital stay and poor clinical outcomes.

**Etiology and Pathogenesis**

The exact reason why delirium occurs is unclear. It is speculated that the mechanism involves the reversible impairment of multiple neurotransmitters. Other possible contributing factors include vision and hearing impairments, psychological stress, and diseases of other organ systems. Delirium has a high mortality rate, ranging between 10% and 76%. Delirium is associated with increased length of hospital stay and poor clinical outcomes.

**Diagnosis and Treatment**

Diagnosis of delirium involves recognition of the syndrome and identification of its causes. The Confusion Assessment Method (CAM) is a validated screening tool developed to quickly and accurately identify delirium. The evaluator assesses the person for the presence of an acute onset or fluctuating course, inattention, disorganized thinking, and altered level of consciousness. Management involves treatment of the underlying disease condition and symptomatic relief through supportive therapy, including removal of any type of restraint (e.g., wrist restraints, Foley catheter), good nutrition and hydration, rest, comfort measures, and emotional support. Prevention of delirium is the overall goal. Avoidance of the devastating and life-threatening acute confusional state is often the key to successful management and treatment.

**IN SUMMARY**

Health care for older adults requires unique considerations, taking into account age-related physiologic changes and specific disease states common in this population. Although aging is not synonymous with disease, the aging process does lend itself to an increased incidence of illness. The overall goal is to assist the older adult in maximizing independence and functional capabilities and minimizing disabilities that can result from various acute and chronic illnesses.

The evaluation of the older adult’s functional abilities is a key component in gerontologic health care. Medical diagnoses alone are incomplete without an assessment of function. When evaluating levels of function, determination of the older adult’s ability to perform ADLs and IADLs should be included.

Among the functional disorders that are common in the older population are urinary incontinence, instability and falls, sensory impairment, and depression, dementia, and delirium. The older adult is especially prone to urinary incontinence because of changes in the micturition cycle that accompany the aging process. Behavioral techniques can be an effective way to treat incontinence problems in the older adult population. Falls are a common source of concern for the older adult population. Although most falls do not result in serious injury, the potential for serious complications and even death is real. Most falls are the result of several risk factors, including age-related biopsychosocial changes, chronic illness, and situational and environmental hazards. Both hearing and visual impairment, which are common in older adults, contribute to communication problems, depression, and social isolation.

Depression is a significant but treatable health problem that often is misdiagnosed and mistreated in the older adult population. Dementia is a syndrome of acquired, persistent impairment in several domains of intellectual function, including memory, language, visuospatial ability, and cognition (i.e., abstraction, calculation, judgment, and problem solving). Although there can be a slight decline in intellectual function with aging, dementia is not a normal aging process. Delirium is an acute confusional disorder developing over a period of hours to days and often is seen as a presenting feature of a physical illness or drug toxicity.

**DRUG THERAPY IN THE OLDER ADULT**

After completing this section of the chapter, you should be able to meet the following objectives:

- Characterize drug therapy in the older adult population.
- List five factors that contribute to adverse drug reactions in the older adult.
- Cite cautions to be used in prescribing medications for the older adult.
Drug therapy in the older adult population is a complex phenomenon influenced by numerous biopsychosocial factors. Older adults are the largest group of consumers of prescription and over-the-counter drugs. Although the older population comprises only about 13% of the US population, they consume one third of all prescription drugs and 50% of all over-the-counter medications. The incidence of adverse drug reactions in older adults is two to three times that found in young adults. This is considered to be a conservative estimate because drug reactions are less well recognized in older adults and reactions often can mimic symptoms of specific disease states.

**Factors Contributing to Adverse Drug Reactions**

Errors in the administration of medications and compliance are common among the community-dwelling older adult population. Reasons for this high rate of errors are numerous and a few factors include:

- Poor manual dexterity
- Failing eyesight
- Lack of understanding about the treatment regimen
- Attitudes and beliefs about medication use
- Mistrust of health care providers
- Forgetfulness or confusion

The role of the health care provider also can contribute to improper medication use. There can be a tendency to treat symptoms with drugs rather than fully investigate the cause of those symptoms. To compound matters, accurate diagnosis of specific disease states can be difficult because older adults tend to underreport symptoms and because presenting symptoms are often atypical.

Age-related physiologic changes also account for adverse effects of medications. In general, the absorption of orally ingested drugs remains essentially unchanged with age, even though the gastric pH is known to rise and gastric emptying time can be delayed. Changes in drug distribution, however, are clinically significant. Because lean body mass and total body water decrease with advancing age, water-soluble drugs such as digoxin and propranolol tend to have a smaller volume of distribution, resulting in higher plasma concentrations for a given dose and increased likelihood of a toxic reaction. Conversely, fat-soluble drugs such as diazepam are more widely distributed and accumulate in fatty tissue owing to an increase in adipose tissue with aging. This can cause a delay in elimination and accumulation of the drug over time (i.e., prolonged half-life) with multiple doses of the same drug. Drug metabolism through the liver is thought to be altered owing to the decrease in hepatic blood flow seen in the older adult. Renal excretion controls the elimination of drugs from the body, and because kidney function declines with age, the rate of drug excretion decreases. This can result in an increased half-life of drugs and is why estimates of creatinine clearance are recommended to determine drug dosing.

Drug use for older adults warrants a cautious approach. “Start low and go slow” is the adage governing drug prescription in geriatric pharmacology. Older adults often can achieve therapeutic results on small doses of medications. If necessary, dosing can then be titrated slowly according to response.

Further complicating matters is the issue of polypharmacy in older adults, who often have multiple disorders that may require multiple drug therapies. Polypharmacy increases the risk of drug interactions and adverse drug reactions and decreases compliance. Drugs and disease states also can interact, causing adverse effects. For example, psychotropic drugs administered to older adults with dementia may cause a worsening of confusion; β-adrenergic blocking agents administered to an individual with chronic obstructive pulmonary disease may induce bronchoconstriction; and NSAIDs given to an older adult with hypertension can raise blood pressure further.

The use of certain types of medications carries a high risk for older adults and should be avoided if possible. In general, long-acting drugs or drugs with prolonged half-lives can be problematic. Many sedatives and hypnotics fit into this category, and drugs such as diazepam and flurazepam should be avoided. Other classes of drugs, such as antidepressants and anxiolytics, may provide the necessary symptomatic relief and may be more appropriate for older adults than sedatives and hypnotics. Use of these agents warrants caution, however, with consideration for the unique pharmacokinetic changes that accompany aging. Drugs that possess anticholinergic properties should also be used with caution. Anticholinergics are used for a variety of conditions. However, side effects such as dry mouth and eyes, blurred vision, and constipation are common. These drugs can also cause more serious side effects, such as confusion, urinary retention, and orthostatic hypotension. Agents that enter the central nervous system, including narcotics and alcohol, can cause a variety of problems, most notably delirium. These problems most likely occur as a result of a decreased central nervous system reserve capacity.

**Strategies to Enhance Therapeutic Effects and Prevent Harm**

Because of the serious implications of medication use in the older adult, strategies need to be used to enhance therapeutic effects and prevent harm. The first step is to include older adults, even those with comorbidities, in clinical trials. Safety and efficacy for older adults should not be extrapolated from studies done on young and middle-aged adults. A representative sample is needed. Careful evaluation of the need for the medication by the health care provider is the next step. Once decided, analysis of the person’s current medication regimen and disease state is necessary to prevent drug–drug interactions, drug–disease interactions, and adverse responses. Screening tools to avoid potentially inappropriate medications in older adults have been developed. The most well known is the Beers criteria. A newer tool, Screening Tool of Older Persons Prescriptions (STOPP), also works to prevent avoidable adverse drug events.

Dosing should be at the low end, and frequency of drug administration should be kept to a minimum to simplify the routine and enhance compliance. Care must be taken to avoid underprescribing as well. In some cases, health care providers
Drugs therapy in the older adult population is a complex phenomenon influenced by numerous biopsychosocial factors. Alterations in pharmacokinetics occur with advancing age and increase the likelihood of toxic reactions. “Start low and go slow” is the adage governing geriatric pharmacology. Centrally acting drugs and drugs with long half-lives should be avoided when possible. Drug–drug interactions, drug–disease interactions, and adverse reactions are increased in older adults. Educating the older adult about drug use is an important factor in ensuring compliance and accurate medication administration.

Chapter 3  Concepts of Altered Health in Older Adults 61

Visit thePoint http://thePoint.lww.com for animations, journal articles, and more!
Jennifer is a 1-day-old infant born after an uncomplicated vaginal delivery to a 46-year-old primipara. She is noted to have poor muscle tone and irregular facies, including up-slanting almond-shaped eyes and a flat facial profile with a depressed nasal bridge. Additionally, she has a heart murmur, and there is concern about a potential heart condition. The pediatrician believes she may have Down syndrome (trisomy 21). A blood sample is drawn for karyotype and sent to the laboratory. Results indicate 47, XX, +21, meaning that Jennifer has 47 chromosomes, including two X chromosomes and an extra copy of chromosome 21. Jennifer and her condition are further discussed within Chapters 4, 6, and 7.
In most organisms, the cell is the smallest functional unit that can retain the characteristics necessary for life. Cells are organized into larger functional units called tissues based on their embryonic origin. These tissues, in turn, combine to form the various body structures and organs. Although the cells of different tissues and organs vary in structure and function, certain characteristics are common to all cells. Cells are remarkably similar in their ability to exchange materials with their immediate environment, obtain energy from organic nutrients, synthesize complex molecules, and replicate themselves. Because most disease processes are initiated at the cellular level, an understanding of cell function is crucial to understanding the disease process. Some diseases affect the cells of a single organ, others affect the cells of a particular tissue type, and still others affect the cells of the entire organism. This chapter discusses the structural and functional components of the cell, integration of cell function and growth, movement of molecules such as ions across the cell membrane, and parenchymal tissue types.
Although diverse in their organization, all eukaryotic cells have in common structures that perform unique functions. Eukaryote cells are larger and have more specific parts in compartments divided by membranes called organelles. The prokaryote cells do not have compartments and they do not possess a demarcated nucleus as the eukaryotes do. When seen under a microscope, three major components of the cell become evident—the nucleus, the cytoplasm, and the cell membrane in the eukaryote cells (Fig. 4.1).

**Protoplasm**

Biologists call the internal matrix of the cell protoplasm. Protoplasm is composed of water, proteins, lipids, carbohydrates, and electrolytes. Two distinct regions of protoplasm exist in the cell:

- The cytoplasm, which lies outside the nucleus
- The karyoplasm or nucleoplasm, which lies inside the nucleus

Water makes up 70% to 85% of the cell’s protoplasm. The second most abundant constituents (10% to 20%) of protoplasm are the cell proteins, which form cell structures and the enzymes necessary for cellular reactions. Proteins can be bound to other compounds to form nucleoproteins, glycoproteins, and lipoproteins. Lipids comprise 2% to 3% of most cells. The most important lipids are the phospholipids and cholesterol, which are mainly insoluble in water; they combine with proteins to form the cell membrane and the membranous barriers that separate different cell compartments. Some cells also contain large quantities of triglycerides. In fat cells, triglycerides can comprise up to 95% of the total cell mass.
This fat represents stored energy, which can be mobilized and used wherever it is needed in the body. Only a few carbohydrates (approximately 1%) are found in the cell, and these serve primarily as a rapid source of energy.1 Potassium, magnesium, phosphate, sulfate, and bicarbonate ions are the major intracellular electrolytes. Small quantities of sodium, chloride, and calcium ions are also present in the cell. These electrolytes participate in reactions that are necessary for the cell’s metabolism, and they help in the generation and transmission of electrochemical impulses in nerve and muscle cells.

**KEY POINTS**

### THE FUNCTIONAL ORGANIZATION OF THE CELL

- The nucleus is the control center for the cell. It also contains most of the hereditary material.
- The organelles, which are analogous to the organs of the body, are contained in the cytoplasm. They include the mitochondria, which supply the energy needs of the cell; the ribosomes, which synthesize proteins and other materials needed for cell function; and the lysosomes and proteasomes, which function as the cell’s digestive system.

**The Nucleus**

The nucleus of the cell appears as a rounded or elongated structure situated near the center of the cell (see Fig. 4.1). All eukaryotic cells have at least one nucleus (prokaryotic cells, such as bacteria, lack a nucleus and nuclear membrane). Some cells contain more than one nucleus; osteoclasts (a type of bone cell) typically contain 12 nuclei or more. The platelet-producing cell, the megakaryocyte, has only one nucleus but usually contains 16 times the normal chromatin amount.1

The nucleus can be regarded as the control center for the cell.1 It contains the deoxyribonucleic acid (DNA) that is essential to the cell because its genes encode the information necessary for the synthesis of proteins that the cell must produce to stay alive. These proteins include structural proteins and enzymes used to synthesize other substances, including carbohydrates and lipids. Genes also represent the individual units of inheritance that transmit information from one generation to another. The nucleus also is the site for the synthesis of the three types of ribonucleic acid (messenger RNA [mRNA], ribosomal RNA [rRNA], and transfer RNA [tRNA]) that move to the cytoplasm and carry out the actual synthesis of proteins. mRNA copies and carries the DNA instructions for protein synthesis to the cytoplasm; rRNA is the site of protein synthesis; and tRNA transports amino acids to the site of proteins synthesis for incorporation into the protein being synthesized.1

Chromatin is the term denoting the complex structure of DNA and DNA-associated proteins dispersed in the nuclear matrix. Depending on its transcriptional activity, chromat in may be condensed as an inactive form of chromatin called heterochromatin or extended as a more active form called euchromatin.1 Because heterochromatic regions of the nucleus stain more intensely than regions consisting of euchromatin, nuclear staining can be a guide to cell activity. Evidence suggests the importance that alteration in the chromatin, along with DNA hypermethylation, in neoplastic progression.2 It seems both of these processes work symbiotically not separately in their role regarding cancer.2

The nucleus also contains the darkly stained round body called the nucleolus.1 The processing of rRNA and its assembly into ribosomes occurs exclusively in the nucleolus. Nucleoli are structures composed of regions from five different chromosomes, each with a part of the genetic code needed for the synthesis of rRNA.1 Euochromatic nuclei and prominent nucleoli are characteristic of cells that are actively synthesizing proteins.

Surrounding the nucleus is the nuclear envelope formed by two (outer and inner) nuclear membranes containing a perinuclear cisternal space between them.1 The inner nuclear membrane is supported by a rigid network of protein filaments that bind to chromosomes and secure their position in the nucleus. The outer nuclear membrane resembles the membrane of the endoplasmic reticulum (ER) and is continuous with it. The nuclear envelope contains many structurally complex circular pores where the two membranes fuse to form a gap filled with a thin protein diaphragm.1 Many classes of molecules, including fluids, electrolytes, RNA, some proteins, and hormones, move in both directions through the nuclear pores. Nuclear pores apparently regulate the bidirectional exchange of molecules between the cytoplasm and the nucleus.1

**The Cytoplasm and Its Organelles**

The cytoplasm surrounds the nucleus, and it is in the cytoplasm that the work of the cell takes place. Cytoplasm is essentially a colloidal solution that contains water, electrolytes, suspended proteins, neutral fats, and glycogen molecules.1 Although not contributing to the cell’s function, pigments may also accumulate in the cytoplasm. Some pigments, such as melanin, which gives skin its color, are normal constituents of the cell. Bilirubin is a normal major pigment of bile; its excess accumulation in cells is evidenced clinically by a yellowish discoloration of the skin and sclera, a condition called jaundice.1

Embedded in the cytoplasm are various organelles, which function as the organs of the cell. These organelles include the ribosomes, ER, Golgi complex, mitochondria, and lysosomes.1

**Ribosomes**

The ribosomes serve as sites of protein synthesis in the cell. They are small particles of nucleoproteins (rRNA and proteins) that are held together by a strand of mRNA to form polyribosomes (also called polysomes).1 Polyribosomes exist as isolated clusters of free ribosomes within the cytoplasm.
Endoplasmic Reticulum

The ER is an extensive system of paired membranes and flat vesicles that connect various parts of the inner cell (Fig. 4.2). Between the paired ER membranes is a fluid-filled space called the matrix. The matrix connects the space between the two membranes of the nuclear envelope, the cell membrane, and various cytoplasmic organelles. It functions as a tubular communication system for transporting various substances from one part of the cell to another. A large surface area and multiple enzyme systems attached to the ER membranes also provide the machinery for a major share of the cell’s metabolic functions.

Two forms of ER exist in cells—rough and smooth. Rough ER is studded with ribosomes attached to specific binding sites on the membrane. Proteins produced by the rough ER are usually destined to become components of lysosomes or other organelles, incorporated into cell membranes, or leave the cell as a secretory protein. The rough ER segregates these proteins from other components of the cytoplasm and modifies their structure for a specific function. For example, the synthesis of both digestive enzymes by pancreatic acinar cells and plasma proteins by liver cells takes place in the rough ER. All cells require a rough ER for the synthesis of lysosomal enzymes.

The smooth ER is free of ribosomes and is continuous with the rough ER. It does not participate in protein synthesis; instead, its enzymes are involved in the synthesis of lipid molecules, regulation of intracellular calcium, and metabolism and detoxification of certain hormones and drugs. It is the site of lipid, lipoprotein, and steroid hormone synthesis. The sarcoplasmic reticulum of skeletal and cardiac muscle cells is a form of smooth ER. Calcium ions needed for muscle contraction are stored and released from cisternae of the sarcoplasmic reticulum. The smooth ER of the liver is involved in glycogen storage and metabolism of lipid-soluble drugs.

The processing ability of the ER is not unlimited. If proteins accumulate in the ER faster than they can be processed, the cell is said to experience “ER stress,” and signaling mechanisms kick in to slow protein production and restore homeostasis. If these homeostatic responses fail, cell death (apoptosis) can result. Defects in the response to ER stress can cause inflammation and even cell death. They have been implicated in inflammatory bowel disease, a genetic form of diabetes mellitus, and a disorder of skeletal muscle known as myositis, as well as many other diseases.

Golgi Complex

The Golgi apparatus, sometimes called the Golgi complex, consists of four or more stacks of thin, flattened vesicles or sacs (see Fig. 4.3). These Golgi bodies are found near the nucleus and function in association with the ER. Substances produced in the ER are carried to the Golgi complex in small, membrane-covered transfer vesicles. Many cells synthesize proteins that are larger than the active product. The Golgi complex modifies these substances and packages them into secretory granules or vesicles. Insulin, for example, is synthesized as a large, inactive proinsulin molecule that is cut apart to produce a smaller, active insulin molecule within the Golgi complex of the beta cells in the pancreas. In addition to producing secretory granules, the Golgi complex is thought to produce large carbohydrate molecules that combine with proteins produced in the rough ER to form glycoproteins. Recent data suggest that the Golgi apparatus has yet another function: it can receive proteins and other substances from the cell surface by a retrograde transport mechanism. Several bacterial toxins, such as Shiga and cholera toxins, and plant toxins, such as ricin, that have cytoplasmic targets have exploited this retrograde pathway.

Lysosomes and Peroxisomes

Lysosomes can be viewed as the digestive system of the cell. These small, membrane-enclosed sacs contain powerful hydrolytic enzymes. These enzymes can break down excess and worn-out cell parts as well as foreign substances that are...
cells undergoing atrophy. Although enzymes in the secondary lysosomes can break down most proteins, carbohydrates, and lipids to their basic constituents, some materials remain undigested. These undigested materials may remain in the cytoplasm as residual bodies or are extruded from the cell by exocytosis. In some long-lived cells, such as neurons and heart muscle cells, large quantities of residual bodies accumulate as lipofuscin granules or age pigment. Other indigestible pigments, such as inhaled carbon particles and tattoo pigments, also accumulate and may persist in residual bodies for decades.

Lysosomes play an important role in the normal metabolism of certain substances in the body. In some inherited diseases known as lysosomal storage diseases, a specific lysosomal enzyme is absent or inactive, in which case the digestion of certain cellular substances (e.g., glucocerebrosides, gangliosides, sphingomyelin) does not occur. As a result, these substances accumulate in the cell. In Tay-Sachs disease, an autosomal recessive disorder, hexosaminidase A, which is the lysosomal enzyme needed for degrading the GM2 ganglioside found in nerve cell membranes, is deficient. Although GM2 ganglioside accumulates in many tissues, such as the heart, liver, and spleen, its accumulation in the nervous system and retina of the eye causes the most damage. There are multiple lysosome storage diseases, and new guidelines are being developed by the American College of Medical Genetics regarding diagnostic criteria and management for Fabry, Gaucher, and Niemann-Pick A/B disease; glycogen storage disease type II; globoid cell leukodystrophy; metachromatic leukodystrophy; and mucopolysaccharidoses types.

Smaller than lysosomes, spherical membrane-bound organelles called peroxisomes contain a special enzyme that degrades peroxides (e.g., hydrogen peroxide). Unlike lysosomes, peroxisomes are not formed by the Golgi apparatus. Peroxisomes are self-replicating like mitochondria and are
Mitochondria

The mitochondria are literally the “power plants” of the cell because they transform organic compounds into energy that is easily accessible to the cell. They do not make energy but extract it from organic compounds. Mitochondria contain the enzymes needed for capturing most of the energy in foodstuffs and converting it into cellular energy. This multistep process is often referred to as cellular respiration because it requires oxygen. Cells store most of this energy as high-energy phosphate bonds in compounds such as adenosine triphosphate (ATP), using it to power the various cellular activities. Mitochondria are found close to the site of energy consumption in the cell (e.g., near the myofibrils in muscle cells). The number of mitochondria in a given cell type varies by the type of activity the cell performs and the energy needed to undertake this activity. For example, a dramatic increase in mitochondria occurs in skeletal muscle repeatedly stimulated to contract.

Mitochondria are composed of two membranes: an outer membrane that encloses the periphery of the mitochondrion and an inner membrane that forms shelflike projections, called cristae (Fig. 4.5). The narrow space between the outer and inner membranes is called the intermembrane space, whereas the large space enclosed by the inner membrane is termed the matrix space. The outer mitochondrial membrane contains a large number of transmembrane porins, through which water-soluble molecules may pass. Because this membrane is

**Proteasomes**

Three major cellular mechanisms are involved in the breakdown of proteins, or proteolysis. One of these is by the previously mentioned endosomal–lysosomal degradation. Another cytoplasmic degradation mechanism is the caspase pathway that is involved in apoptotic cell death. The third method of proteolysis occurs within an organelle called the proteasome. Proteasomes are small organelles composed of protein complexes that are thought to be present in both the cytoplasm and the nucleus. This organelle recognizes misformed and misfolded proteins that have been targeted for degradation, including transcription factors and the cyclins that are important in controlling the cell cycle. It has been suggested that as much as one third of the newly formed polypeptide chains are selected for proteasome degradation because of quality-control mechanisms in the cell.

![Mitochondrion diagram](image-url)

**FIGURE 4.5** Mitochondrion. The inner membrane forms transverse folds called cristae, where the enzymes needed for the final step in adenosine triphosphate (ATP) production (i.e., oxidative phosphorylation) are located. (From McConnell T. H., Hull K. L. (2011). *Human form human function: Essentials of anatomy & physiology* (p. 74). Philadelphia, PA: Lippincott Williams & Wilkins.)
relatively permeable to small molecules, including proteins, the contents of the intermembrane space resemble that of the cytoplasm. The inner membrane contains the respiratory chain enzymes and transport proteins needed for the synthesis of ATP. In certain regions, the outer and inner membranes contact each other, these contact points serve as pathways for proteins and small molecules to enter and leave the matrix space.

Mitochondria contain their own DNA and ribosomes and are self-replicating. Mitochondrial DNA (mtDNA) is found in the mitochondrial matrix and is distinct from the chromosomal DNA found in the nucleus. Also known as the “other human genome,” mtDNA is a double-stranded, circular molecule that encodes the rRNA and tRNA required for intramitochondrial synthesis of the proteins needed for the energy-generating functions of the mitochondria. Although mtDNA directs the synthesis of 13 of the proteins required for mitochondrial function, the DNA of the nucleus encodes the structural proteins of the mitochondria and other proteins needed to carry out cellular respiration.6,9

mtDNA is inherited matrilineally (i.e., from the mother), thus providing a basis for familial lineage studies. Mutations have been found in each of the mitochondrial genes, and an understanding of the role of mtDNA in certain diseases is beginning to emerge. Most tissues in the body depend to some extent on oxidative metabolism and can therefore be affected by mtDNA mutations.6

Mitochondria also function as key regulators of apoptosis or programmed cell death. The initiation of the mitochondrial pathway for apoptosis results from an increase in mitochondrial permeability and the subsequent release of proapoptotic molecules into the cytoplasm. One of these proapoptotic molecules is cytochrome c, which is bound by cardiolipin (a phospholipid).10 It is well known for its role in mitochondrial respiration. In the cytosol, cytochrome c binds to a protein called apoptosis activating factor-1, initiating the molecular events involved in the apoptosis cascade. Other apoptotic proteins also enter the cytoplasm, where they bind to and neutralize the various apoptotic inhibitors, whose normal function is to block the apoptotic cascade. Both the formation of reactive oxygen species (ROS) (e.g., peroxide) and the activation of the p53 tumor suppressor gene by DNA damage or other means initiate apoptotic signaling through the mitochondria. ROS has been determined to be the etiology of cell injury to multiple diseases.10 Dysregulated apoptosis (too little or too much) has been implicated in a wide range of diseases, including cancer, in which there is an inappropriately low rate of apoptosis, and neurodegenerative diseases, in which there is an increased or excessive rate of apoptosis.

The Cytoskeleton

Besides its organelles, the cytoplasm contains a network of microtubules, microfilaments, intermediate filaments, and thick filaments (Fig. 4.6).6 Because they control cell shape and movement, these structures are a major component of the structural elements called the cytoskeleton, which participates in the movement of entire cells.

Microtubules

Microtubules are formed from protein subunits called tubulin. They are long, stiff, hollow, cylindrical structures, 25 nm in outer diameter with a lumen 15 nm in diameter.9 Each microtubule consists of parallel protofilaments, each composed of α- and β-tubulin dimers.9 Microtubules are dynamic structures that can rapidly disassemble in one location and reassemble in another. During the reassembly process the tubulin dimers polymerize in an end-to-end fashion to form protofilaments. As a result of the polymerization process, each microtubule possesses a nongrowing “minus” end and a rapidly growing “plus” end. During the disassembly process, the tubulin dimers dissociate from the protofilaments and form a pool of free tubulin in the cytoplasm.9 This pool is used in the polymerization process for reassembly of the protofilaments.9

Microtubules function in many ways, including the development and maintenance of cell form. They participate in intracellular transport mechanisms, including axoplasmic transport in neurons and melanin dispersion in pigment cells of the skin. Other functions include formation of the basic structure for several complex cytoplasmic organelles, including the centrioles, basal bodies, cilia, and flagella9 (Fig. 4.7).

The plant alkaloid colchicine binds to tubulin molecules and prevents the assembly of microtubules. This compound stops cell mitosis by interfering with formation of the mitotic spindle and is often used for cytogenetic (chromosome) studies. It is also used in treating gout to prevent migration of neutrophils and to lower their ability to respond
Cilia and Flagella. Cilia and flagella are microtubule-filled cellular extensions whose enclosing membrane is continuous with the cell membrane. Ciliated cells typically possess a large number of cilia, whereas flagellated cells have only one flagellum. In humans, the spermatozoa are the only cell type with flagella. Cilia are found on the apical (luminal) surfaces of many epithelial linings, including the nasal sinuses and bronchi in the upper respiratory system. They also play a prominent role in sensory tissues such as the photoreceptor proteins in the eye, the odorant receptors of the olfactory epithelium, and the kinocilium on the hair cells in the inner ear. Cilia also act in sensory roles at critical stages of embryonic development, and they are essential for the normal functioning of many tissues, including the kidney, during postnatal life. Recent research has linked the pathogenesis of a condition called polycystic kidney disease to a genetic defect in the cilia of the renal tubular cells.

A motile cilium contains nine sets of doublet microtubules that form a hollow cylinder surrounding a central pair of singlet microtubules. The outer doublet microtubules contain ATP motor–driven complexes that cause the adjacent microtubule doublets to slide past each other. All of these microtubules and their associated proteins are anchored to a basal body that is responsible for the formation of a core structure called the axoneme. The axoneme serves as the internal framework that supports the cilium and provides a structure on which mechanical movement is generated. Recent evidence suggests that not all cilia contain this internal structure, and some may be missing the central pair of microtubules. Cilia lacking the central core of microtubules are often called primary cilia and are immotile.

Cilia and flagella are assembled through a process called intraflagellar transport, during which large protein complexes are transported along the ciliary microtubules from the basal body to the ciliary tip and then back to the basal body. These protein complexes are thought to carry ciliary precursors from their site of synthesis in the cytoplasm to their site of assembly at the tip of the cilium. Genetic defects can result in improper ciliary assembly and, as a result, the cilia may be nonfunctional. One of these disorders, the immotile cilia syndrome, impairs sperm motility, causing male sterility while also immobilizing the cilia of the respiratory tract, thus interfering with clearance of inhaled bacteria, leading to a chronic lung disease called bronchiectasis. Kartagener syndrome is an example of immotile cilia syndrome and involves diffuse bronchiolitis, sinus aplasia, and situs inversus totalis, which is a reversal of the thorax and abdomen organs.

Microfilaments

Microfilaments are thin, threadlike cytoplasmic structures. Three classes of microfilaments exist:

1. Thin microfilaments, which are equivalent to the thin actin filaments in muscle
2. Intermediate filaments, which are a heterogeneous group of filaments with diameter sizes between those of the thick and thin filaments
3. Thick myosin filaments, which are present in muscle cells, but may also exist temporarily in other cells.
Muscle contraction depends on the interaction between the thin actin filaments and thick myosin filaments. Microfilaments are present in the superficial zone of the cytoplasm in most cells. Contractile activities involving the microfilaments and associated thick myosin filaments contribute to the movement of the cytoplasm and cell membrane during endocytosis and exocytosis. Microfilaments are also present in the microvilli of the intestine. The intermediate filaments assist in supporting and maintaining the asymmetric shape of cells. Examples of intermediate filaments are the keratin filaments that are found anchored to the cell membrane of epidermal keratinocytes of the skin and the glial filaments that are found in astrocytes and other glial cells of the nervous system. The neurofibrillary tangle found in the brain in Alzheimer disease contains microtubule-associated proteins and neurofilaments, evidence of a disrupted neuronal cytoskeleton.

The Cell (Plasma) Membrane

The cell is enclosed in a thin membrane that separates the intracellular contents from the extracellular environment. To differentiate it from the other cell membranes, such as the mitochondrial or nuclear membranes, the cell membrane is often called the plasma membrane. In many respects, the plasma membrane is one of the most important parts of the cell. It acts as a semipermeable structure that separates the intracellular and extracellular environments. It provides receptors for hormones and other biologically active substances, participates in the electrical events that occur in nerve and muscle cells, and aids in the regulation of cell growth and proliferation.

The cell membrane is a dynamic and fluid structure consisting of an organized arrangement of lipids, carbohydrates, and proteins (Fig. 4.8). A main structural component of the membrane is its lipid bilayer. It is a bimolecular layer that consists primarily of phospholipids, with glycolipids and cholesterol. This lipid bilayer provides the basic fluid structure of the membrane and serves as a relatively impermeable barrier to all but lipid-soluble substances. Approximately 75% of the lipids are phospholipids, each with a hydrophilic (water-soluble) head and a hydrophobic (water-insoluble) tail. Phospholipid molecules along with the glycolipids are aligned such that their hydrophilic heads face outward on each side of the membrane and their hydrophobic tails project toward the middle of the membrane. The hydrophilic heads retain water and help cells stick to each other. At normal body temperature, the viscosity of the lipid component of the membrane is equivalent to that of olive oil. The presence of cholesterol stiffens the membrane.

Although the lipid bilayer provides the basic structure of the cell membrane, proteins carry out most of the specific functions. The integral proteins span the entire lipid bilayer and are essentially part of the membrane. Because most of the integral proteins pass directly through the membrane, they are also referred to as transmembrane proteins. A second type of protein, the peripheral proteins, is bound to one or the other side of the membrane and does not pass into the lipid bilayer. Removal of peripheral proteins from the membrane surface usually causes damage to the membrane.

The manner in which proteins are associated with the cell membrane often determines their function. Thus, peripheral proteins are associated with functions involving the inner or outer side of the membrane where they are found. Several peripheral proteins serve as receptors or are involved in intracellular signaling systems. By contrast, only the transmembrane proteins can function on both sides of the membrane or transport molecules across it.

![Figure 4.8](image-url)
Many integral transmembrane proteins form the ion channels found on the cell surface. These channel proteins have a complex morphology and are selective with respect to the substances they transmit. Mutations in these channel proteins, often called channelopathies, are responsible for a host of genetic disorders. For example, in cystic fibrosis, the primary defect resides in an abnormal chloride channel, which results in increased sodium and water reabsorption that causes respiratory tract secretions to thicken and occlude the airways. A recent discovery showed there are specific water channels or pores called aquaporins in the plasma membrane. It is now known that aquaporin disorders are responsible for a number of diseases, including nephrogenic diabetes insipidus.

A fuzzy-looking layer surrounding the cell surface is called the cell coat, or glycocalyx. The structure of the glycocalyx consists of long, complex carbohydrate chains attached to protein molecules that penetrate the outside portion of the membrane (i.e., glycoproteins); outward-facing membrane lipids (i.e., glycolipids); and carbohydrate-binding proteins called lectins. These proteins [lectins] are responsible for a variety of activities and have antitumor, immunomodulatory, antifungal, and HIV-1 reverse transcriptase inhibitory processes. The cell coat participates in cell-to-cell recognition and adhesion. It contains tissue transplant antigens that label cells as self or nonself. The cell coat of a red blood cell contains the ABO blood group antigens. An intimate relationship exists between the cell membrane and the cell coat. If the cell coat is enzymatically removed, the cell remains viable and can generate a new cell coat, but damage to the cell membrane usually results in cell death.

IN SUMMARY

The cell is a remarkably autonomous structure that functions in a strikingly similar manner to that of the total organism. In most cells, a single nucleus controls cell function and is the mastermind of the cell. It contains DNA, which provides the information necessary for the synthesis of the various proteins that the cell must produce to stay alive and to transmit information from one generation to another. The nucleus also is the site for the synthesis of the three types of RNA (mRNA, rRNA, tRNA) that move to the cytoplasm and carry out the actual synthesis of proteins.

The cytoplasm contains the cell’s organelles and cytoskeleton. Ribosomes serve as sites for protein synthesis in the cell. The ER functions as a tubular communication system that transports substances from one part of the cell to another and as the site of protein (rough ER), carbohydrate, and lipid (smooth ER) synthesis. Golgi bodies modify materials synthesized in the ER and package them into secretory granules for transport within the cell or for export from the cell. Lysosomes, which are viewed as the digestive system of the cell, contain hydrolytic enzymes that digest worn-out cell parts and foreign materials. They are membranous structures formed in the Golgi complex from hydrolytic enzymes synthesized in the rough ER. Another organelle, the proteasome, digests misfolded and misfolded proteins. The mitochondria serve as power plants for the cell because they transform food energy into ATP, to power cell activities. Mitochondria contain their own extrachromosomal DNA, important in the synthesis of mitochondrial RNAs and proteins used in oxidative metabolism. Besides its organelles, the cytoplasm contains a network of microtubules, microfilaments, intermediate filaments, and thick filaments. Microtubules are slender, stiff tubular structures that influence cell shape, provide a means of moving organelles through the cytoplasm, and effect movement of the cilias and of chromosomes during cell division. Microfilaments, which are thin, threadlike cytoplasmic structures, include the actin and myosin filaments that participate in muscle contraction.

The plasma membrane is a lipid bilayer that surrounds the cell and separates it from its surrounding external environment. Although the lipid bilayer provides the basic structure of the cell membrane, proteins carry out most of the specific functions. Transmembrane proteins frequently form transport channels for ions and other substances, whereas peripheral proteins often function as receptor sites for signaling molecules. A fuzzy-looking layer, the cell coat or glycocalyx, surrounds the cell surface. It contains tissue antigens and participates in cell-to-cell recognition and adhesion.

INTEGRATION OF CELL FUNCTION AND REPLICATION

After completing this section of the chapter, you should be able to meet the following objectives:

- Trace the pathway for cell communication, beginning at the receptor and ending with the effector response, and explain why the process is often referred to as signal transduction.
- Describe the phases of mitotic cell division.
- Relate the function of ATP to cell metabolism.

Cell Communication

Cells in multicellular organisms need to communicate with one another to coordinate their function and control their growth. The human body has several means of transmitting information between cells. These mechanisms include direct communication between adjacent cells through gap junctions, autocrine and paracrine signaling, and endocrine or synaptic signaling. Autocrine signaling occurs when a cell releases a chemical into the extracellular fluid that affects its own activity (Fig. 4.9). With paracrine signaling, enzymes rapidly metabolize the chemical mediators, and therefore they act mainly on nearby cells. Endocrine signaling relies on hormones carried in the
Cell Receptors

Signaling systems consist of receptors that reside either in the cell membrane (surface receptors) or within the cells (intracellular receptors). Receptors are activated by a variety of extracellular signals or first messengers, including neurotransmitters, protein hormones and growth factors, steroids, and other chemical messengers. Some lipid-soluble chemical messengers move through the membrane and bind to cytoplasmic or nuclear receptors to exert their physiologic effects. Signaling systems also include transducers and effectors that are involved in conversion of the signal into a physiologic response. The pathway may include additional intracellular mechanisms, called second messengers. Many molecules involved in signal transduction are proteins. A unique property of proteins that allows them to function in this way is their ability to change their shape or conformation, thereby changing their function and consequently the functions of the cell. Proteins often accomplish these conformational changes through enzymes called protein kinases that catalyze the phosphorylation of amino acids in the protein structure.

Cell Surface Receptors

Each cell type in the body contains a distinctive set of surface receptors that enable it to respond to a complementary set of signaling molecules in a specific, preprogrammed way. These proteins are not static components of the cell membrane; they increase or decrease in number according to the needs of the cell. When excess chemical messengers are present, the number of active receptors decreases in a process called down-regulation; when there is a deficiency of the messenger, the number of active receptors increases through up-regulation. Three known classes of cell surface receptor proteins exist: G-protein–linked, ion-channel–linked, and enzyme-linked.

G-Protein–Linked Receptors. With more than a 1000 members, G-protein–linked receptors are the largest family of cell surface receptors. Although many intercellular messengers exist, they rely on the intermediary activity of a separate class of membrane-bound regulatory proteins to convert external signals (first messengers) into internal signals (second messengers). Because these regulatory proteins bind to guanine nucleotides such as guanine diphosphate (GDP) and guanine triphosphate (GTP), they are called G proteins. G-protein–linked receptors mediate cellular responses for numerous types of first messengers, including proteins, small peptides, amino acids, and fatty acid derivatives such as the prostaglandins.

Although there are differences among the G-protein–linked receptors, all share a number of features. They all have a ligand-binding extracellular receptor component, which functions as a signal discriminator by recognizing a specific first messenger, and they all undergo conformational changes with receptor binding that activates the G protein.
monophosphate (cAMP). It is activated by the enzyme adenyl cyclase, which generates cAMP by transferring phosphate groups from ATP to other proteins. This transfer changes the conformation and function of these proteins. Such changes eventually produce the cell response to the first messenger, whether it is a secretion, muscle contraction or relaxation, or a change in metabolism. Sometimes, it is the opening of membrane channels involved in calcium or potassium influx.

**Enzyme-Linked Receptors.** Like G-protein–linked receptors, enzyme-linked receptors are transmembrane proteins with their ligand-binding site on the outer surface of the cell membrane. Instead of having a cytosolic domain that associates with a G protein, their cytosolic domain either has intrinsic enzyme activity or associates directly with an enzyme. There are several classes of enzyme-linked receptors, including those that activate or have tyrosine kinase activity. Enzyme-linked receptors mediate cellular responses such as calcium influx, increased sodium–potassium exchange, and stimulation of glucose and amino acid uptake. Insulin, for example, acts by binding to a surface receptor with tyrosine kinase activity.

The signaling cascades generated by the activation of tyrosine kinase receptors are also involved in the function of growth factors. As their name implies, many growth factors are important messengers in signaling cell replacement and cell growth. Most of the growth factors belong to one of three groups: factors that foster the multiplication and development of various cell types (e.g., epidermal growth factor and vascular endothelial growth factor); cytokines, which are important in the regulation of the immune system; and colony-stimulating factors, which regulate the proliferation and maturation of white and red blood cells. All growth factors function by binding to specific receptors that deliver signals to target cells. These signals have two general effects: they stimulate the transcription of many genes that were silent in resting cells, and they regulate the entry of cells into the cell cycle and their passage through the cell cycle.

**Ion-Channel–Linked Receptors.** Ion-channel–linked receptors are involved in the rapid synaptic signaling between electrically excitable cells. Many neurotransmitters mediate this type of signaling by transiently opening or closing ion channels formed by integral proteins in the cell membrane. This type of signaling is involved in the transmission of impulses in nerve and muscle cells.

**Intracellular Receptors**

Some messengers, such as thyroid hormone and steroid hormones, do not bind to membrane receptors but move directly across the lipid layer of the cell membrane and are carried to the cell nucleus, where they influence DNA activity. Many of these hormones bind to a cytoplasmic receptor, and the receptor–hormone complex is carried to the nucleus. In (Fig. 4.10). All G proteins are found on the cytoplasmic side of the cell membrane, and all incorporate the GTPase cycle, which functions as a molecular switch that exists in two states. In its activated (on) state, the G protein has a high affinity for GTP, and in its inactivated (off) state, it binds GDP.

At the molecular level, G proteins are heterotrimeric (i.e., they have three subunits) proteins (see Fig. 4.10). The three subunits are designated alpha (α), beta (β), and gamma (γ). The α subunit can bind either GDP or GTP and contains the GTPase activity. GTPase is an enzyme that converts GTP with its three phosphate groups to GDP with its two phosphate groups.

When GDP is bound to the α subunit, the G protein is inactive; when GTP is bound, it is active. The activated G protein has GTPase activity, so eventually the bound GTP is hydrolyzed to GDP, and the G protein reverts to its inactive state. Receptor activation causes the α subunit to dissociate from the receptor and the β and γ subunits and transmit the signal from the first messenger to its effector protein. Often, the effector is an enzyme that converts an inactive precursor molecule into a second messenger, which diffuses into the cytoplasm and carries the signal beyond the cell membrane. A common second messenger is cyclic adenosine monophosphate (cAMP). It is activated by the enzyme adenyl cyclase, which generates cAMP by transferring phosphate groups from ATP to other proteins. This transfer changes the conformation and function of these proteins. Such changes eventually produce the cell response to the first messenger, whether it is a secretion, muscle contraction or relaxation, or a change in metabolism. Sometimes, it is the opening of membrane channels involved in calcium or potassium influx.

**Enzyme-Linked Receptors.** Like G-protein–linked receptors, enzyme-linked receptors are transmembrane proteins with their ligand-binding site on the outer surface of the cell membrane. Instead of having a cytosolic domain that associates with a G protein, their cytosolic domain either has intrinsic enzyme activity or associates directly with an enzyme. There are several classes of enzyme-linked receptors, including those that activate or have tyrosine kinase activity. Enzyme-linked receptors mediate cellular responses such as calcium influx, increased sodium–potassium exchange, and stimulation of glucose and amino acid uptake. Insulin, for example, acts by binding to a surface receptor with tyrosine kinase activity.

The signaling cascades generated by the activation of tyrosine kinase receptors are also involved in the function of growth factors. As their name implies, many growth factors are important messengers in signaling cell replacement and cell growth. Most of the growth factors belong to one of three groups: factors that foster the multiplication and development of various cell types (e.g., epidermal growth factor and vascular endothelial growth factor); cytokines, which are important in the regulation of the immune system; and colony-stimulating factors, which regulate the proliferation and maturation of white and red blood cells. All growth factors function by binding to specific receptors that deliver signals to target cells. These signals have two general effects: they stimulate the transcription of many genes that were silent in resting cells, and they regulate the entry of cells into the cell cycle and their passage through the cell cycle.

**Ion-Channel–Linked Receptors.** Ion-channel–linked receptors are involved in the rapid synaptic signaling between electrically excitable cells. Many neurotransmitters mediate this type of signaling by transiently opening or closing ion channels formed by integral proteins in the cell membrane. This type of signaling is involved in the transmission of impulses in nerve and muscle cells.

**Intracellular Receptors**

Some messengers, such as thyroid hormone and steroid hormones, do not bind to membrane receptors but move directly across the lipid layer of the cell membrane and are carried to the cell nucleus, where they influence DNA activity. Many of these hormones bind to a cytoplasmic receptor, and the receptor–hormone complex is carried to the nucleus. In
the nucleus, the receptor–hormone complex binds to DNA, thereby increasing transcription of mRNA. The mRNAs are translated in the ribosomes, with the production of increased amounts of proteins that alter cell function.\(^7\)

### The Cell Cycle and Cell Division

The life cycle of a cell is called the **cell cycle**. It is usually divided into five phases:

1. **G\(_0\)**
2. **G\(_1\)**
3. **S**
4. **G\(_2\)**
5. **M** (Fig. 4.11)

G\(_0\) is the stage when the cell may leave the cell cycle and either remain in a state of inactivity or reenter the cell cycle at another time. G\(_1\) is the stage during which the cell begins to prepare for mitosis through DNA and protein synthesis and an increase in organelle and cytoskeletal elements. The S phase is the synthesis phase, during which DNA replication occurs and the centrioles begin to replicate. G\(_2\) is the premitotic phase and is similar to G\(_1\) in terms of RNA activity and protein synthesis. The M phase is the phase during which cell mitosis occurs.\(^9\) Tissues may be composed primarily of quiescent cells in G\(_0\), but most tissues contain a combination of cells that are continuously moving through the cell cycle and quiescent cells that occasionally enter the cell cycle. Nondividing cells, such as neurons and skeletal and cardiac muscle cells, have left the cell cycle and are not capable of mitotic division in postnatal life.\(^9\)

Cell division, or **mitosis**, is the process during which a parent cell divides and each daughter cell receives a chromosomal karyotype identical to the parent cell.\(^9\) Cell division gives the body a means of replacing cells that have a limited life span such as skin and blood cells, increasing tissue mass during periods of growth, and providing for tissue repair and wound healing.

#### Remember
Jennifer, the newborn from the unit opener case study? When children are born with specific phenotype characteristics, such as poor muscle tone, depressed nasal bridge, a flat facial profile, and up-slanting almond-shaped eyes, a karyotype is performed. The karyotype results indicate a positive trisomy 21.

Mitosis is a dynamic and continuous process. It is divided into four stages—prophase, metaphase, anaphase, and telophase (Fig. 4.12). The phase during which the cell is not undergoing division is called **interphase**. During prophase, the chromosomes become visible because of increased coiling of the DNA, the two centrioles replicate, and a pair moves to each side of the cell. Simultaneously, the microtubules of the mitotic spindle appear between the two pairs of centrioles. Later in prophase, the nuclear envelope and nucleolus disappear. **Metaphase** involves the organization of the chromosome pairs in the midline of the cell and the formation of a mitotic spindle composed of microtubules. **Anaphase** is the period during which separation of the chromosome pairs occurs, with the microtubules pulling one member of each pair of 46 chromosomes toward the opposite cell pole. Cell division or **cytokinesis** is completed after **telophase**, the stage during which the mitotic spindle vanishes and a new nuclear membrane develops and encloses each complete set of chromosomes.\(^9\)

Cell division is controlled by changes in the concentrations and activity of three major groups of intracellular proteins:

1. **Cyclins**
2. **Cyclin-dependent kinases (CDKs)**
3. **Anaphase-promoting complex**\(^9\)

The central components of the cell cycle control system are the CDKs, whose activity depends on their association with the regulatory units called cyclins. Oscillations in the activity of the various CDKs lead to initiation of the different phases of the cell cycle. Cell division is also controlled by several external factors, including the presence of cytokines, various growth factors, or even adhesion factors when the cell is associated with other cells in a tissue.\(^9\)
Cell Metabolism and Energy Sources

Energy is the ability to do work. Cells use oxygen to transform the breakdown products of the foods we eat into the energy needed for muscle contraction; the transport of ions and other molecules across cell membranes; and the synthesis of enzymes, hormones, and other macromolecules. Energy metabolism refers to the processes by which fats, proteins, and carbohydrates from the foods we eat are converted into energy or complex energy sources in the cell. Catabolism and anabolism are the two phases of metabolism. Catabolism consists of breaking down stored nutrients and body tissues to produce energy. Anabolism is a constructive process in which more complex molecules are formed from simpler ones.

The special carrier for cellular energy is ATP. ATP molecules consist of adenosine, a nitrogenous base; ribose, a five-carbon sugar; and three phosphate groups (Fig. 4.13). The phosphate groups are attached by two high-energy bonds. Large amounts of free energy are released when ATP is hydrolyzed to form adenosine diphosphate (ADP), an adenosine molecule that contains two phosphate groups. The free energy liberated from the hydrolysis of ATP is used to drive reactions that require free energy. Energy from foodstuffs is used to convert ADP back to ATP. Because energy can be “saved or spent” using ATP, ATP is often called the energy currency of the cell.

![Image of ATP structure](https://example.com/atp.png)  

**FIGURE 4.13** • ATP is the major source of cellular energy. (A) Each molecule of ATP contains two high-energy bonds, each containing about 12 kcal of potential energy. (B) The high-energy ATP bonds are in constant flux. They are generated by substrate (glucose, amino acid, and fat) metabolism and are consumed as the energy is expended.
Energy transformation takes place within the cell through two types of energy production—the anaerobic (i.e., without oxygen) glycolytic pathway, occurring in the cytoplasm, and the aerobic (i.e., with oxygen) pathway, occurring in the mitochondria. The anaerobic glycolytic pathway serves as an important prelude to the aerobic pathway. Both pathways involve oxidation–reduction reactions involving an electron donor, which is oxidized in the reaction, and an electron acceptor, which is reduced in the reaction. In energy metabolism, the breakdown products of carbohydrate, fat, and protein metabolism donate electrons and are oxidized, and the coenzymes nicotinamide adenine dinucleotide (NAD+) and flavin adenine dinucleotide (FAD) accept electrons and are reduced.

**Anaerobic Metabolism**

Glycolysis is the process by which energy is liberated from glucose. It is an important energy provider for cells that lack mitochondria, the cell organelle in which aerobic metabolism occurs. This process also provides energy in situations when delivery of oxygen to the cell is delayed or impaired. Glycolysis involves a sequence of reactions that convert glucose to pyruvate, with the concomitant production of ATP from ADP. The net gain of energy from the glycolysis of one molecule of glucose is two ATP molecules. Although comparatively inefficient as to energy yield, the glycolytic pathway is important during periods of decreased oxygen delivery, as occurs in skeletal muscle during the first few minutes of exercise.

Glycolysis requires the presence of NAD+. Important end products of glycolysis are pyruvate and NADH (the reduced form of NAD+) plus H+. When oxygen is present, pyruvate moves into the aerobic mitochondrial pathway, and NADH + H+ delivers its electron and proton (H+) to the oxidative electron transport system. Transfer of electrons from NADH + H+ to the electron transport system allows the glycolytic process to continue by facilitating the regeneration of NAD+. Under anaerobic conditions, such as cardiac arrest or circulatory shock, pyruvate is converted to lactic acid, which diffuses out of the cells into the extracellular fluid. Conversion of pyruvate to lactic acid is reversible, and after the oxygen supply has been restored, lactic acid is converted back to pyruvate and used directly for energy or to synthesize glucose.

Much of the conversion of lactic acid occurs in the liver, but a small amount can occur in other tissues. The liver removes lactic acid from the bloodstream and converts it to glucose in a process called gluconeogenesis. This glucose is released into the bloodstream to be used again by the muscles or by the central nervous system (CNS). Heart muscle is also efficient in converting lactic acid to pyruvic acid and then using the pyruvic acid for fuel. Pyruvic acid is a particularly important source of fuel for the heart during heavy exercise when the skeletal muscles are producing large amounts of lactic acid and releasing it into the bloodstream.

**Aerobic Metabolism**

Aerobic metabolism occurs in the cell’s mitochondria and involves the citric acid cycle and the electron transport chain. It is here that the carbon compounds from the fats, proteins, and carbohydrates in our diet are broken down and their electrons combined with molecular oxygen to form carbon dioxide and water as energy is released. Unlike lactic acid, which is an end product of anaerobic metabolism, carbon dioxide and water are generally harmless and easily eliminated from the body. In a 24-hour period, oxidative metabolism produces 300 to 500 mL of water.

The citric acid cycle, sometimes called the tricarboxylic acid (TCA) or Krebs cycle, provides the final common pathway for the metabolism of nutrients. In the citric acid cycle, which takes place in the matrix of the mitochondria, an activated two-carbon molecule of acetyl-coenzyme A (acetyl-CoA) condenses with a four-carbon molecule of oxaloacetic acid and moves through a series of enzyme-mediated steps. This process produces hydrogen atoms and carbon dioxide. As hydrogen is generated, it combines with NAD+ or FAD for transfer to the electron transport system. In the citric acid cycle, each of the two pyruvate molecules formed in the cytoplasm from one molecule of glucose yields another molecule of ATP along with two molecules of carbon dioxide and eight electrons that end up in three molecules of NADH + H+ and one of FADH2. Besides pyruvate from the glycolysis of glucose, products of amino acid and fatty acid degradation enter the citric acid cycle and contribute to the generation of ATP.

Oxidative metabolism, which supplies 90% of the body’s energy needs, takes place in the electron transport chain in the mitochondria. The electron transport chain oxidizes NADH + H+ and FADH2 and donates the electrons to oxygen, which is reduced to water. Energy from reduction of oxygen is used for phosphorylation of ADP to ATP. Because the formation of ATP involves the addition of a high-energy phosphate bond to ADP, the process is sometimes called oxidative phosphorylation.

Among the members of the electron transport chain are several iron-containing molecules called cytochromes. Each cytochrome is a protein that contains a heme structure similar to that of hemoglobin. The last cytochrome complex is cytochrome oxidase, which passes electrons from cytochrome c to oxygen. Cytochrome oxidase has a lower binding affinity for oxygen than myoglobin (the intracellular heme-containing oxygen carrier) or hemoglobin (the heme-containing oxygen transporter in erythrocytes in the blood). Thus, oxygen is pulled from erythrocytes to myoglobin and from myoglobin to cytochrome oxidase, where it is reduced to H2O. Although iron-deficiency anemia is characterized by decreased levels of hemoglobin, the iron-containing cytochromes in the electron transport chain in tissues such as skeletal muscle are affected as well. Thus, the fatigue that develops in iron-deficiency anemia results, in part, from impaired function of the electron transport chain.
Cell metabolism is the process that converts dietary fuels from carbohydrates, proteins, and fats into ATP, which provides for the energy needs of the cell. ATP is formed through three major pathways: (1) the glycolytic pathway, (2) the citric acid cycle, and (3) the electron transport chain. In fuel metabolism, which is an oxidation–reduction reaction, the fuel donates electrons and is oxidized, and the coenzymes NAD⁺ and FAD accept electrons and are reduced.

**Glycolytic Pathway**

Glycolysis, which occurs in the cytoplasm of the cell, involves the splitting of the six-carbon glucose molecule into two three-carbon molecules of pyruvic acid. Because the reaction that splits glucose requires two molecules of ATP, there is a net gain of only two molecules of ATP from each molecule of glucose that is metabolized. The process is anaerobic and does not require oxygen (O₂) or produce carbon dioxide (CO₂). When O₂ is present, pyruvic acid moves into the mitochondria, where it enters the aerobic citric acid cycle. Under anaerobic conditions, pyruvate is converted to lactic acid, allowing glycolysis to continue as a means of supplying cells with ATP when O₂ is lacking.

**Citric Acid Cycle**

Under aerobic conditions, both of the pyruvic acid molecules formed by the glycolytic pathway enter the mitochondria, where each combines with acetyl-coenzyme to form acetyl-coenzyme A (acetyl-CoA). The formation of acetyl-CoA begins the reactions that occur in the citric acid cycle. Some reactions release CO₂ and some transfer electrons from the hydrogen atom to NADH or FADH. In addition to pyruvic acid from the glycolysis of glucose, fatty acid and amino acid breakdown products can also enter the citric acid cycle. Fatty acids, which are the major source of fuel in the body, are oxidized by a process called beta oxidation to acetyl-CoA for entry into the citric acid cycle.
At the completion of the citric acid cycle, each glucose molecule has yielded four new molecules of ATP (two from glycolysis and two from the citric acid cycle). In fact, the principal function of these earlier stages is to make the electrons ($e^-$) from glucose and other food substrates available for oxidation. Oxidation of the electrons carried by NADH and FADH$_2$ is accomplished through a series of enzymatically catalyzed reactions in the mitochondrial electron transport chain. During these reactions, protons (H$^+$) combine with O$_2$ to form water (H$_2$O), and large amounts of energy are released and used to add a high-energy phosphate bond to ADP, converting it to ATP. There is a net yield of 36 molecules of ATP from 1 molecule of glucose (2 from glycolysis, 2 from the citric acid cycle, and 32 from the electron transport chain). In general, the net amount of ATP formed from each gram of protein that is metabolized is less than for glucose, whereas that obtained from fat is greater (e.g., each 16-carbon fatty acid molecule yields about 129 molecules of ATP).

**Electron Transport Chain**

Cells communicate with each other by chemical messenger systems. In some tissues, chemical messengers move from cell to cell through gap junctions without entering the extracellular fluid. Other types of chemical messengers bind to receptors on or near the cell surface. Three classes of cell surface receptor proteins are known: G-protein–linked, ion-channel–linked, and enzyme-linked. G-protein–linked receptors rely on a class of molecules called G proteins that function as an on–off switch to convert external signals (first messengers) into internal signals (second messengers). Ion-channel–linked signaling is mediated by neurotransmitters that transiently open or close ion channels formed by integral proteins in the cell membrane. Enzyme-linked receptors interact with certain peptide hormones, such as insulin and growth factors, and directly initiate the activity of the intracellular protein–tyrosine kinase enzyme.

The life cycle of a cell is called the cell cycle. It is usually divided into five phases: G$_0$, the resting phase; G$_s$, during which the cell begins to prepare for division through DNA and protein synthesis; the S or synthetic phase, during which DNA replication occurs; G$_2$, which is the premitotic phase and is similar to G$_1$ regarding RNA and protein synthesis; and the M phase, during which cell division occurs. Cell division, or mitosis, is the process during which a parent cell divides into two daughter cells, each receiving an identical pair of chromosomes. The process of mitosis is dynamic and continuous and is divided into four stages: prophase, metaphase, anaphase, and telophase.

Metabolism is the process whereby carbohydrates, fats, and proteins from the foods we eat are broken down and subsequently converted into the energy needed for cell function. Energy is converted to ATP, the energy currency of the cell. Two sites of energy conversion are present in cells: the anaerobic glycolytic pathway in the cytoplasm and the aerobic pathways in the mitochondria. The most efficient of these pathways is the aerobic citric acid cycle and electron transport chain in the mitochondria. This pathway requires oxygen and produces carbon dioxide and water as end products. The glycolytic pathway in the cytoplasm involves the breakdown of glucose to form ATP. This pathway can function without oxygen by producing lactic acid.
After completing this section of the chapter, you should be able to meet the following objectives:

• Discuss the mechanisms of membrane transport associated with diffusion, osmosis, endocytosis, and exocytosis and compare them with active transport mechanisms.
• Describe the basis for membrane potentials.

The cell membrane serves as a barrier that controls which substances enter and leave the cell. This barrier function allows materials that are essential for cellular function to enter the cell while excluding those that are harmful. It is responsible for differences in the composition of intracellular and extracellular fluids.

**Movement of Substances across the Cell Membrane**

Movement through the cell membrane occurs in essentially two ways: passively, without an expenditure of energy, or actively, using energy-consuming processes. The cell membrane can also engulf a particle, forming a membrane-coated vesicle; this membrane-coated vesicle is moved into the cell by endocytosis or out of the cell by exocytosis.

**Passive Movement**

Passive movement of particles or ions across the cell membrane is directly influenced by chemical or electrical gradients and does not require an expenditure of energy. A difference in the number of particles on either side of the membrane creates a chemical gradient and a difference in charged particle or ions creates an electrical gradient. Chemical and electrical gradients are often linked and are called electrochemical gradients.

**Diffusion.** Diffusion refers to the process by which molecules and other particles in a solution become widely dispersed and reach a uniform concentration because of energy created by their spontaneous kinetic movements (Fig. 4.14A). Electrolytes and other substances move from an area of higher to an area of lower concentration. With ions, diffusion is affected by energy supplied by their electrical charge. Lipid-soluble molecules such as oxygen, carbon dioxide, alcohol, and fatty acids become dissolved in the lipid matrix of the cell membrane and diffuse through the membrane in the same manner that diffusion occurs in water. Other substances diffuse through minute pores of the cell membrane. The rate of movement depends on how many particles are available for diffusion and the velocity of the kinetic movement of the particles. The number of openings in the cell membrane through which the particles can move also determines transfer rates. Temperature changes the motion of the particles; the greater the temperature, the greater is the thermal motion of the molecules. Thus, diffusion increases in proportion to increased temperature.
Osmosis. Most cell membranes are semipermeable in that they are permeable to water but not to all solute particles. Water moves through water channels (aquaporins) in a semipermeable membrane along a concentration gradient, moving from an area of higher to one of lower concentration (see Fig. 4.14B). This process is called osmosis, and the pressure that water generates as it moves through the membrane is called osmotic pressure.7

Osmosis is regulated by the concentration of nondiffusible particles on either side of a semipermeable membrane. When there is a difference in the concentration of particles, water moves from the side with the lower concentration of particles and higher concentration of water to the side with the higher concentration of particles and lower concentration of water. The movement of water continues until the concentration of particles on both sides of the membrane is equally diluted or until the hydrostatic (osmotic) pressure created by the movement of water opposes its flow.

Facilitated Diffusion. Facilitated diffusion occurs through a transport protein that is not linked to metabolic energy (see Fig. 4.14C). Some substances, such as glucose, cannot pass unassisted through the cell membrane because they are not lipid soluble or are too large to pass through the membrane’s pores. These substances combine with special transport proteins at the membrane’s outer surface, are carried across the membrane attached to the transporter, and then released on the inside of the membrane. In facilitated diffusion, a substance can move only from an area of higher concentration to one of lower concentration. The rate at which a substance moves across the membrane because of facilitated diffusion depends on the difference in concentration between the two sides of the membrane. Also important are the availability of transport proteins and the rapidity with which they can bind and release the substance being transported. It is thought that insulin, which facilitates the movement of glucose into cells, acts by increasing the availability of glucose transporters in the cell membrane.7

Active Transport and Cotransport

Active transport mechanisms involve the expenditure of energy. The process of diffusion describes particle movement from an area of higher concentration to one of lower concentration, resulting in an equal distribution across the cell membrane. Sometimes, however, different concentrations of a substance are needed in the intracellular and extracellular fluids. For example, to function, a cell requires a much higher intracellular concentration of potassium ions than is present in the extracellular fluid, while maintaining a much lower intracellular concentration of sodium ions than the extracellular fluid. In these situations, energy is required to pump the ions “uphill” or against their concentration gradient. When cells use energy to move ions against an electrical or chemical gradient, the process is called active transport.7

The active transport system studied in the greatest detail is the sodium–potassium (Na+/K+)–ATPase pump (see Fig. 4.14D). This pump moves sodium from inside the cell to the extracellular region, the pump also returns potassium to the inside, of the cell.9 Energy used to pump sodium out of the cell and potassium into the cell is obtained by splitting and releasing energy from the high-energy phosphate bond in ATP by the enzyme ATPase. Were it not for the activity of the Na+/K+–ATPase pump, the osmotically active sodium particles would accumulate in the cell, causing cellular swelling because of an accompanying influx of water.

Two types of active transport systems exist: primary active transport and secondary active transport. In primary active transport, the source of energy (e.g., ATP) is used directly in the transport of a substance. Secondary active transport mechanisms harness the energy derived from the primary active transport of one substance, usually sodium, for the cotransport of a second substance. For example, when sodium ions are actively transported out of a cell by primary active transport, a large concentration gradient develops (i.e., high concentration on the outside and low on the inside). This concentration gradient represents a large storehouse of energy because sodium ions are always attempting to diffuse into the cell. Similar to facilitated diffusion, secondary transport mechanisms use membrane transport proteins. These proteins have two binding sites, one for sodium and the other for the substance undergoing secondary transport. Secondary transport systems are classified into two groups: cotransport or symport systems, in which the sodium ion and the solute are transported in the same direction, and countertransport or antiport systems, in which the sodium ion and the solute are transported in the opposite direction (Fig. 4.15).9

An example of cotransport occurs in the intestine, where the absorption of glucose and amino acids is coupled with sodium transport.

Endocytosis and Exocytosis

Endocytosis is the process by which cells engulf materials from their surroundings. It includes pinocytosis and phagocytosis. Pinocytosis involves the ingestion of small solid or fluid particles. The particles are engulfed into small, membrane-surrounded vesicles for movement into the cytoplasm. The process of pinocytosis is important in the transport of proteins and strong solutions of electrolytes (see Fig. 4.14E).6

Phagocytosis literally means “cell eating” and can be compared with pinocytosis, which means “cell drinking.” It involves the engulfment and subsequent killing or degradation of microorganisms or other particulate matter. During phagocytosis, a particle contacts the cell surface and is surrounded on all sides by the cell membrane, forming a phagocytic vesicle or phagosome. Once formed, the phagosome breaks away from the cell membrane and moves into the cytoplasm, where it eventually fuses with a lysosome, allowing the ingested material to be degraded by lysosomal enzymes. Certain cells, such as macrophages and polymorphonuclear leukocytes (neutrophils), are adept at engulfing and disposing of invading organisms, damaged cells, and unneeded extracellular constituents.6
Ion Channels

The electrical charge on small ions such as sodium and potassium makes it difficult for these ions to move across the lipid layer of the cell membrane. However, rapid movement of these ions is required for many types of cell functions, such as nerve activity. This is accomplished by facilitated diffusion through selective ion channels. Ion channels are integral proteins that span the width of the cell membrane and are normally composed of several polypeptides or protein subunits that form a gating system. Specific stimuli cause the protein subunits to undergo conformational changes to form an open channel or gate through which the ions can move (Fig. 4.16). In this way, ions do not need to cross the lipid-soluble portion of the membrane but can remain in the aqueous solution that fills the ion channel. Ion channels are highly selective; some channels allow only for passage of sodium ions, and others are selective for potassium, calcium, or chloride ions. Specific interactions between the ions and the sides of the channel can produce an extremely rapid rate of ion movement. For example, ion channels can become negatively charged, promoting the rapid movement of positively charged ions.9

The plasma membrane contains two basic groups of ion channels: leakage channels and gated channels. Leakage channels are open even in the unstimulated state, whereas gated channels open and close in response to specific stimuli. Three main types of gated channels are present in the plasma membrane: voltage-gated channels, which have electrically operated channels that open when the membrane potential changes beyond a certain point; ligand-gated channels, which are chemically operated and respond to specific receptor-bound ligands, such as the neurotransmitter acetylcholine; and mechanically gated channels, which open or close in response to such mechanical stimulations as vibrations, tissue stretching, or pressure (see Fig. 4.16).9

Membrane Potentials

Electrical potentials exist across the membranes of most cells in the body. Because these potentials occur at the level of the cell membrane, they are called membrane potentials.6 In excitable tissues, such as nerve or muscle cells, changes in the membrane potential are necessary for generation and conduction of nerve impulses and muscle contraction. In other types of cells, such as glandular cells, changes in the membrane potential contribute to hormone secretion and other functions.

Electrical potentials, measured in volts (V), describe the ability of separated electrical charges of opposite polarity (+ and −) to do work. The potential difference is the difference between the separated charges. The terms potential difference and voltage are synonymous.6 Voltage is always measured with respect to two points in a system. For example, the voltage in a car battery (6 or 12 V) is the potential difference between the two battery terminals. Because the total amount of charge that can be separated by a biologic membrane is small, the potential differences are small and are measured in millivolts (mV), or 1/1000 of a volt. Potential differences across the cell membrane can be measured by inserting a very fine electrode into the cell and another into the extracellular fluid surrounding the cell and connecting the two electrodes to a voltmeter. The movement of charge between two points is called current. It occurs when a potential difference has been
When using this formula, it is generally assumed that the potential in the extracellular fluid outside the membrane remains at zero potential and the Nernst potential is inside the membrane. The sign of the potential is negative (−) if a positively charged ion diffuses from the inside of the membrane to the outside, and it is positive (+) if a positively charged ion diffuses from the outside to the inside of the membrane.

In the resting or unexcited state, when the membrane is highly permeable to potassium, the concentration of potassium ions inside the cell is approximately 35 times greater than outside. Because of the large concentration gradient existing across the cell membrane, potassium ions tend to diffuse outward. As they do so, they carry their positive charges with them, causing the inside to become negative in relation to the outside. This new potential difference repels further outward movement of the positively charged potassium ion. The membrane is said to be polarized during this stage because of the negative membrane potential that is present. The same phenomenon occurs during an action potential, when the membrane becomes highly permeable to sodium, allowing the positively charged ion to diffuse to the interior of the cell. The inflowing sodium ions produce a reversal in the normal RMP to one of the opposite polarity (positive on the inside and negative on the outside). This is called depolarization.

Extracellular and intracellular fluids are electrolyte solutions containing approximately 150 to 160 mmol/L of positively charged ions and an equal concentration of negatively charged ions. These current-carrying ions are responsible for generating and conducting membrane potentials. Usually, a small excess of charged ions exists at the outer surface of the cell membrane. This is represented as positive charges on the outside of the membrane and is balanced by an equal number of negative charges on the inside of the membrane. Because of the extreme thinness of the cell membrane, the accumulation of these ions at the surfaces of the membrane contributes to the establishment of a resting membrane potential (RMP).

A diffusion potential describes the voltage generated by ions that diffuse across the cell membrane. Two conditions are necessary for a membrane potential to occur by diffusion: the membrane must be selectively permeable, allowing a single type of ion to diffuse through membrane pores, and the concentration of the diffusible ion must be greater on one side of the membrane than on the other. An equilibrium potential is one in which no net movement of ions occurs because the diffusion and electrical forces are exactly balanced.

When using this formula, it is generally assumed that the potential in the extracellular fluid outside the membrane remains at zero potential and the Nernst potential is inside the membrane. The sign of the potential is negative (−) if a positively charged ion diffuses from the inside of the membrane to the outside, and it is positive (+) if a positively charged ion diffuses from the outside to the inside of the membrane.

In the resting or unexcited state, when the membrane is highly permeable to potassium, the concentration of potassium ions inside the cell is approximately 35 times greater than outside. Because of the large concentration gradient existing across the cell membrane, potassium ions tend to diffuse outward. As they do so, they carry their positive charges with them, causing the inside to become negative in relation to the outside. This new potential difference repels further outward movement of the positively charged potassium ion. The membrane is said to be polarized during this stage because of the negative membrane potential that is present. The same phenomenon occurs during an action potential, when the membrane becomes highly permeable to sodium, allowing the positively charged ion to diffuse to the interior of the cell. The inflowing sodium ions produce a reversal in the normal RMP to one of the opposite polarity (positive on the inside and negative on the outside). This is called depolarization.
Electrochemical potentials are present across the membranes of virtually all cells in the body. Some cells, such as nerve and muscle cells, are capable of generating rapidly changing electrical impulses, and these impulses are used to transmit signals along their membranes. In other cells, such as glandular cells, membrane potentials are used to signal the release of hormones or activate other functions of the cell. Generation of membrane potentials relies on (1) diffusion of current-carrying ions, (2) development of an electrochemical equilibrium, (3) establishment of a RMP, and (4) triggering of action potentials.

**Diffusion Potentials**

A diffusion potential is a potential difference generated across a membrane when a current-carrying ion, such as the potassium (K⁺) ion, diffuses down its concentration gradient. Two conditions are necessary for this to occur: (1) the membrane must be selectively permeable to a particular ion, and (2) the concentration of the diffusible ion must be greater on one side of the membrane than the other.

The magnitude of the diffusion potential, measured in millivolts, depends on the size of the concentration gradient. The sign (+ or −) or polarity of the potential depends on the diffusing ion. It is negative on the inside when a positively charged ion such as K⁺ diffuses from the inside to the outside of the membrane, carrying its charge with it.

**Equilibrium Potentials**

An equilibrium potential is the membrane potential that exactly balances and opposes the net diffusion of an ion down its concentration gradient. As a cation diffuses down its concentration gradient, it carries its positive charge across the membrane, thereby generating an electrical force that will eventually retard and stop its diffusion. An electrochemical equilibrium is one in which the chemical forces driving diffusion and the repelling electrical forces are exactly balanced so that no further diffusion occurs. The equilibrium potential (EMF, electromotive force) can be calculated by inserting the inside and outside ion concentrations into the Nernst equation.
Action Potentials

Action potentials involve rapid changes in the membrane potential. Each action potential begins with a sudden change from the negative RMP to a positive threshold potential, causing an opening of the membrane channels for Na⁺ (or other ions of the action potential). Opening of the Na⁺ channels allows large amounts of the positively charged Na⁺ ions to diffuse to the interior of the cell, causing the membrane potential to undergo depolarization or a rapid change to positive on the inside and negative on the outside. This is quickly followed by closing of Na⁺ channels and opening of the K⁺ channels, which leads to a rapid efflux of K⁺ from the cell and reestablishment of the RMP.
particles require bonding with a ligand, and the process is called receptor-mediated endocytosis. Exocytosis involves the removal of large particles from the cell and is essentially the reverse of endocytosis.

Ion channels are integral transmembrane proteins that span the width of the cell membrane and are normally composed of polypeptide or protein subunits that form a gating system. Many ions can diffuse through the cell membrane only if conformational changes occur in the membrane proteins that comprise the ion channel. Two basic groups of ion channels exist: leakage channels and ligand-, voltage-, and mechanically gated channels.

Electrochemical potentials exist across the membranes of most cells in the body. The RMP results from the selective permeability of the cell membrane to potassium; the presence of nondiffusible anions inside the cell membrane; and the activity of the Na+/K+–ATPase membrane pump, which extrudes sodium ions from inside the membrane and returns potassium ions to the inside.

There are two main factors that contribute to the generation of membrane potentials: a difference in the concentration of ions inside and outside the membrane and the permeability of the membrane. An equilibrium or diffusion potential is one in which no net movement of ions occurs because the diffusion and electrical forces are exactly balanced. The RMP (negative on the inside and positive on the outside) is essentially a potassium equilibrium potential that results from the selective permeability of the membrane to potassium and the large difference in potassium ion concentration that exists between the intracellular and extracellular compartments. During an action potential, the cell membrane becomes highly permeable to sodium, causing it to depolarize and reverse its polarity, becoming positive on the inside and negative on the outside.

The Nernst Equation for Calculating an Equilibrium Potential

The following equation, known as the Nernst equation, can be used to calculate the equilibrium potential (electromotive force [EMF]) in millivolts [mV] of a univalent ion at body temperature of 37°C.

\[
EMF (mV) = -61 \times \log_{10} \left( \frac{\text{ion concentration inside}}{\text{ion concentration outside}} \right)
\]

For example, if the concentration of an ion inside the membrane is 100 mmol/L and the concentration outside the membrane is 10 mmol/L, the EMF (mV) for that ion would be \(-61 \times \log_{10} (100/10) \) \([\log_{10} of 10 is 1]\). Therefore, it would take 61 mV of charge inside the membrane to balance the diffusion potential created by the concentration difference across the membrane for the ion.

The EMF for potassium ions using a normal estimated intracellular concentration of 140 mmol/L and a normal extracellular concentration of 4 mmol/L is \(-94 mV\):

\[
-94 \text{ mV} = -61 \times \log_{10} (140 \text{ mmol inside}/4 \text{ mmol outside})
\]

This value assumes the membrane is permeable only to potassium. This value approximates the \(-70 to -90 \text{ mV resting membrane potential}\) for nerve fibers measured in laboratory studies.

When a membrane is permeable to several different ions, the diffusion potential reflects the sum of the equilibrium potentials for each of the ions.

IN SUMMARY

Movement of materials across the cell’s membrane is essential for survival of the cell. Diffusion is a process by which substances such as ions move from an area of greater concentration to one of lesser concentration. Osmosis refers to the diffusion of water molecules through a semipermeable membrane along a concentration gradient. Facilitated diffusion is a passive process, in which molecules that cannot normally pass through the cell’s membrane do so with the assistance of a carrier molecule. Another type of transport, called active transport, requires the cell to expend energy in moving ions against a concentration gradient. Two types of active transport exist, primary and secondary, both of which require carrier proteins. The Na+/K+–ATPase pump is the best-known mechanism of active transport. Endocytosis is a process by which cells engulf materials from the surrounding medium. Small particles are ingested by a process called pinocytosis and larger particles by phagocytosis. Some

BOD TISSUES

After completing this section of the chapter, you should be able to meet the following objectives:

- Explain the process of cell differentiation in terms of development of organ systems in the embryo and the continued regeneration of tissues in postnatal life.
- Describe the characteristics of the four different tissue types.
- Characterize the composition and functions of the extracellular components of tissue.

In the preceding sections, we discussed the individual cell, its metabolic processes, and mechanisms of communication
and replication. Although cells are similar, their structure and function vary according to the special needs of the body. For example, muscle cells perform different functions from skin cells or nerve cells. Groups of cells that are closely associated in structure and have common or similar functions are called tissues. Four categories of tissue exist:

1. Epithelium
2. Connective (supportive) tissue
3. Muscle
4. Nerve

These tissues do not exist in isolated units, but in association with each other and in variable proportions, forming different structures and organs of the body. This section provides a brief overview of the cells in each of these four tissue types, the structures that hold these cells together, and the extracellular matrix in which they live.

Cell Differentiation

After conception, the fertilized ovum undergoes a series of divisions, ultimately forming approximately 200 different cell types. The formation of different types of cells and the disposition of these cells into tissue types is called cell differentiation, a process controlled by a system that switches genes on and off. Embryonic cells must become different to develop into all of the various organ systems, and they must remain different after the signal that initiated cell diversification has disappeared. The process of cell differentiation is controlled by cell memory, which is maintained through regulatory proteins contained in the individual members of a particular cell type. Cell differentiation also involves the sequential activation of multiple genes and their protein products. This means that after differentiation has occurred, the tissue type does not revert to an earlier stage of differentiation. The process of cell differentiation normally moves forward, producing cells that are more specialized than their predecessors. Usually, highly differentiated cell types, such as skeletal muscle and nervous tissue, lose their ability to undergo cell division in postnatal life.

Although most cells differentiate into specialized cell types, many tissues contain a few stem cells that apparently are only partially differentiated. These stem cells are still capable of cell division and serve as a reserve source for specialized cells throughout the life of the organism. They are the major source of cells that make regeneration possible in some tissues. Stem cells have varying abilities to differentiate. Some tissues, such as skeletal muscle tissue, lack sufficient numbers of undifferentiated cells and have limited regenerative capacity. Stem cells of the hematopoietic (blood) system have the greatest potential for differentiation. These cells can potentially reconstitute the entire blood-producing and immune systems. They are the major ingredient in bone marrow transplants. Other stem cells, such as those that replenish the mucosal surface of the gastrointestinal tract, are less general but can still differentiate.

KEY POINTS

**ORGANIZATION OF CELLS INTO TISSUES**

- Cells with a similar embryonic origin or function are often organized into larger functional units called tissues, and these tissues in turn associate with other, dissimilar tissues to form the various organs of the body.
- Nervous tissue, which consists of two cell types, nerve cells or neurons and glial or supporting cells, is distributed throughout the body and serves as the body’s communication system. The nervous system is divided anatomically into the CNS, which consists of the brain and spinal cord, and the peripheral nervous system (PNS), which is composed of nerve tissue outside the CNS.

**Embryonic Origin of Tissue Types**

All of the approximately 200 different types of body cells can be classified into four basic or primary tissue types: epithelial, connective, muscle, and nervous (Table 4.1). These basic tissue types are often described by their embryonic origin.

The embryo is essentially a three-layered tubular structure (Fig. 4.17). The outer layer of the tube is called the ectoderm; the middle layer, the mesoderm; and the inner layer, the endoderm. All of the adult body tissues originate from these three cellular layers. Epithelium has its origin in all three embryonic layers, connective tissue and muscle develop mainly from the mesoderm, and nervous tissue develops from the ectoderm.

**Epithelial Tissue**

Epithelial tissue covers the body’s outer surface and lines the internal closed cavities (including blood vessels) and body tubes that communicate with the exterior (gastrointestinal, respiratory, and genitourinary tracts). Epithelium also forms the secretory portion of glands and their ducts.

**Origin and Characteristics**

Epithelial tissue is derived from all three embryonic layers. Most epithelia of the skin, mouth, nose, and anus are derived from the ectoderm. Linings of the respiratory tract, gastrointestinal tract, and glands of the digestive system are of endodermal origin. The endothelial lining of blood vessels originates from the mesoderm. Many types of epithelial tissue retain the ability to differentiate and undergo rapid proliferation for replacing injured cells.

The cells that make up epithelium have three general characteristics:

- They are characterized by three distinct surfaces: a free surface or apical surface, a lateral surface, and a basal surface.
areas, and the basal surface rests on the basement membrane anchoring the cell to the surrounding connective tissue.

Epithelial tissue is avascular (i.e., without blood vessels) and must therefore receive oxygen and nutrients from the capillaries of the connective tissue on which the epithelial tissue rests (see Fig. 4.18). To survive, epithelial tissue must be kept moist. Even the seemingly dry skin epithelium is kept moist by a nonvitalized, waterproof layer of superficial skin cells called keratin, which prevents evaporation of moisture from the deeper living cells.
**Basement Membrane.** Underneath all types of epithelial tissue is an extracellular matrix, called the *basement membrane*. A basement membrane consists of the basal lamina and an underlying reticular layer. The terms *basal lamina* and *basement membrane* are often used interchangeably. Epithelial cells have strong intracellular protein filaments (i.e., cytoskeleton) that are important in transmitting mechanical stresses from one cell to another.6

**Cell Junctions and Cell-to-Cell Adhesions.** Cells of epithelial tissue are tightly bound together by specialized junctions. These specialized junctions enable the cells to form barriers to the movement of water, solutes, and cells from one body compartment to the next. Three basic types of intercellular junctions are observed in epithelial tissues: continuous tight junctions, adhering junctions, and gap junctions (Fig. 4.19).

Continuous tight or occluding junctions (i.e., *zonula occludens*), which are found only in epithelial tissue, seal the surface membranes of adjacent cells together. This type of intercellular junction prevents materials such as macromolecules in the intestinal contents from entering the intercellular space.6

Adhering junctions represent sites of strong adhesion between cells. The primary role of adhering junctions may be that of preventing cell separation. Adhering junctions are not restricted to epithelial tissue; they provide adherence between adjacent cardiac muscle cells as well. Adhering junctions are found as continuous, beltlike adhesive junctions (i.e., *zonula adherens*) or scattered, spotlike adhesive junctions, called desmosomes (i.e., *macula adherens*). A special feature of the adhesion belt junction is that it provides an anchoring site to the cell membrane for microfilaments.6

In epithelial desmosomes, bundles of keratin-containing intermediate filaments (i.e., tonofilaments) are anchored to the junction on the cytoplasmic area of the cell membrane. A primary disease of desmosomes is pemphigus, which is caused by a buildup of antibodies to desmosome proteins.10
Affected people have skin and mucous membrane blistering. Hemidesmosomes, which resemble a half-desmosome, are another type of junction. They are found at the base of epithelial cells and help attach the epithelial cell to the underlying connective tissue.

Gap or nexus junctions involve the close adherence of adjoining cell membranes with the formation of channels that link the cytoplasm of the two cells. Gap junctions are not unique to epithelial tissue; they play an essential role in many types of cell-to-cell communication. Because they are low-resistance channels, gap junctions are important in cell-to-cell conduction of electrical signals (e.g., between cells in sheets of smooth muscle or between adjacent cardiac muscle cells, where they function as electrical synapses). These multiple communication channels also enable ions and small molecules to pass directly from one cell to another.6,9

Types of Epithelium

Epithelial tissues are classified according to the shape of the cells and the number of layers that are present: simple, stratified, and pseudostratified. The terms squamous (thin and flat), cuboidal (cube shaped), and columnar (resembling a column) refer to the cells’ shape (Fig. 4.20).5

**Simple Epithelium.** Simple epithelium contains a single layer of cells, all of which rest on the basement membrane. Simple squamous epithelium is adapted for filtration; it is found lining the blood vessels, lymph nodes, and alveoli of the lungs. The single layer of squamous epithelium lining the heart and blood vessels is known as the endothelium. A similar type of layer, called the mesothelium, forms the serous membranes that line the pleural, pericardial, and peritoneal cavities and cover the organs of these cavities. A simple cuboidal epithelium is found on the surface of the ovary and in the thyroid. Simple columnar epithelium lines the intestine. One form of a simple columnar epithelium has hairlike projections called cilia, often with specialized mucus-secreting cells called goblet cells. This form of simple columnar epithelium lines the airways of the respiratory tract.6

**Stratified and Pseudostratified Epithelia.** Stratified epithelium contains more than one layer of cells, with only the deepest layer resting on the basement membrane. It is designed to protect the body surface. Stratified squamous keratinized epithelium makes up the epidermis of the skin. Keratin is a tough, fibrous protein found as filaments in the outer cells of skin. A stratified squamous keratinized epithelium is made up of many
layers. The layers closest to the underlying tissues are cuboidal or columnar. The cells become more irregular and thinner as they move closer to the surface. Surface cells become totally filled with keratin and die, are sloughed off, and then replaced by the deeper cells. A stratified squamous nonkeratinized epithelium is found on moist surfaces such as the mouth and tongue. Stratified cuboidal and columnar epithelia are found in the ducts of salivary glands and the larger ducts of the mammary glands. In smokers, the normal columnar ciliated epithelial cells of the trachea and bronchi are often replaced with stratified squamous epithelium cells that are better able to withstand the irritating effects of cigarette smoke.

**Pseudostratified epithelium** is a type of epithelium in which all of the cells are in contact with the underlying intercellular matrix, but some do not extend to the surface. A pseudostratified ciliated columnar epithelium with goblet cells forms the lining of most of the upper respiratory tract. All of the tall cells reaching the surface of this type of epithelium are either ciliated cells or mucus-producing goblet cells. The basal cells that do not reach the surface serve as stem cells for ciliated and goblet cells. Transitional epithelium is a stratified epithelium characterized by cells that can change shape and become thinner when the tissue is stretched. Such tissue can be stretched without pulling the superficial cells apart. Transitional epithelium is well adapted for the lining of organs that are constantly changing their volume, such as the urinary bladder.

**Glandular Epithelium.** Glandular epithelial tissue is formed by cells specialized to produce a fluid secretion. This process is usually accompanied by the intracellular synthesis of macromolecules. The chemical nature of these macromolecules is variable. The macromolecules typically are stored in the cells in small, membrane-bound vesicles called secretory granules. For example, glandular epithelia can synthesize, store, and secrete proteins (e.g., insulin), lipids (e.g., adrenocortical hormones, secretions of the sebaceous glands), and complexes of carbohydrates and proteins (e.g., saliva). Less common are secretions that require minimal synthetic activity, such as those produced by the sweat glands.

All glandular cells arise from surface epithelia by means of cell proliferation and invasion of the underlying connective tissue, and all release their contents or secretions into the extracellular compartment. Exocrine glands, such as the sweat glands and lactating mammary glands, retain their connection with the surface epithelium from which they originated. This connection takes the form of epithelium-lined tubular ducts through which the secretions pass to reach the surface. Exocrine glands are often classified according to the way secretory products are released by their cells. In holocrine-type cells (e.g., sebaceous glands), the glandular cell ruptures, releasing its entire content into the duct system. New generations of cells are replaced by mitosis of basal cells. Merocrine- or eccrine-type glands (e.g., salivary glands, exocrine glands of the pancreas) release their glandular products by exocytosis. In apocrine secretions (e.g., mammary glands, certain sweat glands), the apical portion of the cell, along with small portions of the cytoplasm, is pinched off the glandular cell. Endocrine glands are epithelial structures that have had their connection with the surface obliterated during development. These glands are ductless and produce secretions (i.e., hormones) that move directly into the bloodstream.
Connective or Supportive Tissue

Connective or supportive tissue is the most abundant tissue in the body. As its name suggests, it connects and binds or supports the various tissues. Connective tissue is unique in that its cells produce the extracellular matrix that supports and holds tissues together. The capsules that surround organs of the body are composed of connective tissue. Bone, adipose tissue, and cartilage are specialized types of connective tissue that function to support the soft tissues of the body and store fat. The proximity of the extracellular matrix to blood vessels allows it to function as an exchange medium through which nutrients and metabolic wastes pass.

Origin and Characteristics

Most connective tissues is derived from the embryonic mesoderm, but some is derived from the neural crest, a derivative of the ectoderm. During embryonic development, mesodermal cells migrate from their site of origin and then surround and penetrate the developing organ. These cells are called mesenchymal cells, and the tissue they form is called mesenchyme. Tissues derived from embryonic mesenchymal cells include bone, cartilage, and adipose (fat) cells. Besides providing the source or origin of most connective tissues, mesenchyme develops into other structures such as blood cells and blood vessels. Connective tissue cells include fibroblasts, chondroblasts, osteoblasts, hematopoietic stem cells, blood cells, macrophages, mast cells, and adipocytes. The matrix of the umbilical cord is composed of a second type of embryonic mesoderm called mucous connective tissue or Wharton jelly.

Types of Connective Tissue

Adult connective tissue can be divided into two types: connective tissue proper, which is the focus of the discussion in this chapter, and specialized connective tissue (cartilage, bone, and blood cells), which is discussed in other chapters. There are four recognized types of connective tissue proper: loose (areolar), adipose, reticular, and dense connective tissue.

Loose Connective Tissue. Loose connective tissue, also known as areolar tissue, is soft and pliable. It fills spaces between muscle sheaths and forms a layer that encases blood and lymphatic vessels (Fig. 4.21). Areolar connective tissue supports the epithelial tissues and provides the means by which these tissues are nourished. In an organ containing functioning epithelial tissue and supporting connective tissue, the term parenchymal tissue is used to describe the functioning epithelium as opposed to the connective tissue framework, or stroma.

Loose connective tissue is characterized by an abundance of ground substance and tissue fluid housing the fixed connective tissue cells: fibroblasts, mast cells, adipose or fat cells, macrophages, and leukocytes. Loose connective tissue cells secrete substances that form the extracellular matrix that supports and connects body cells. Fibroblasts are the most abundant of these cells. They are responsible for the synthesis of the fibrous and gel-like substance that fills the intercellular spaces of the body and for the production of collagen, elastic, and reticular fibers.

The basal lamina is a special type of intercellular matrix that is present where connective tissue contacts the tissue it supports. It is visible only with an electron microscope and is produced by the epithelial cells. In many locations, reticular fibers, produced by the connective tissue cells, are associated with the basal lamina. Together the basal lamina and the reticular layer form the basement membrane seen by light microscopy. A basement membrane is found along the interface between connective tissue and muscle fibers, on Schwann cells of the PNS, on the basal surface of endothelial cells, and on fat cells. These basement membranes bond cells to the underlying or surrounding connective tissues, serve as selective filters for particles that pass between connective tissue and other cells, and contribute to cell regeneration and repair.

Adipose Tissue. Adipose tissue is a special form of connective tissue in which adipocytes predominate. Adipocytes do not generate an extracellular matrix but maintain a large intracellular space. These cells store large quantities of triglycerides and are the largest repository of energy in the body. Adipose tissue helps fill spaces between tissues and helps to keep organs in place. The subcutaneous fat helps to shape the body. Because fat is a poor conductor of heat, adipose tissue serves as thermal insulation for the body. Adipose tissue exists in two forms: unilocular and multilocular. Unilocular
(white) adipose tissue is composed of cells in which the fat is contained in a single, large droplet in the cytoplasm. Multilocular (brown) adipose tissue is composed of cells that contain multiple droplets of fat and numerous mitochondria.

Reticular Connective Tissue. Reticular tissue is characterized by a network of fibers interspersed with fibroblasts and macrophages. The fibroblasts synthesize type III collagen fibers. Reticular tissue forms the architecture of liver sinusoids, adipose tissue, bone marrow, and lymphoid tissues such as the spleen.

Dense Connective Tissue. Dense connective tissue exists in two forms: dense irregular and dense regular. Dense irregular connective tissue consists of the same components found in loose connective tissue, but exhibits a predominance of collagen fibers and fewer cells. This type of tissue can be found in the dermis of the skin (i.e., reticular layer), the fibrous capsules of many organs, and the fibrous sheaths of cartilage (i.e., perichondrium) and bone (i.e., periosteum). It also forms the fascia that invests muscles and organs. Dense regular connective tissues are rich in collagen fibers and form the tendons and aponeuroses that join muscles to bone or other muscles and the ligaments that join bone to bone.

Muscle Tissue

Muscle tissue, whose primary function is contraction, is responsible for movement of the body and its parts and for changes in the size and shape of internal organs. Muscle tissue contains two types of fibers that are responsible for contraction: thin and thick filaments. The thin filaments are composed primarily of actin, whereas the thick filaments are composed of myosin. The two types of myofilaments occupy the bulk of the cytoplasm, which in muscle cells is called the sarcoplasm.9

There are three types of muscle tissues: skeletal, cardiac, and smooth. Skeletal and cardiac muscles are striated muscles, in which the actin and myosin filaments are arranged in large, parallel arrays in bundles, giving the muscle fibers a striped or striated appearance when observed with a microscope. Smooth muscle lacks striations and is found in the iris of the eye, the walls of blood vessels, hollow organs such as the stomach and urinary bladder, and hollow tubes, such as the ureters and common bile duct, that connect internal organs.9

Neither skeletal nor cardiac muscle can undergo the mitotic activity needed to replace injured cells. Smooth muscle, however, may proliferate and undergo mitotic activity. Some increases in smooth muscle are physiologic, as occurs in the uterus during pregnancy. Other increases, such as the increase in smooth muscle that occurs in the arteries of peripheral organs during pregnancy. Other increases, such as the increase in smooth muscle that occurs in the arteries of persons with chronic hypertension, are pathologic.

Although the three types of muscle tissue differ significantly in structure, contractile properties, and control mechanisms, they have many similarities. In the following section, the structural properties of skeletal muscle are presented as the prototype of striated muscle tissue. Smooth muscle and the ways in which it differs from skeletal muscle are also discussed.

Skeletal Muscle

Skeletal muscle is the most abundant tissue in the body, accounting for 40% to 45% of the total body weight.9 Most skeletal muscles are attached to bones, and their contractions are responsible for movements of the skeleton. Each skeletal muscle is a discrete organ made up of hundreds or thousands of muscle fibers. At the periphery of skeletal muscle fibers, randomly scattered satellite cells are found. They represent a source of undifferentiated myoblast cells that may be involved in the limited regeneration capabilities of skeletal muscle. Although muscle fibers predominate, substantial amounts of connective tissue, blood vessels, and nerve fibers are also present.

Organization and Structure. In an intact muscle, several different layers of connective tissue hold the individual muscle fibers together. Skeletal muscles such as the biceps brachii are surrounded by a dense, irregular connective tissue covering called the epimysium (Fig. 4.22A). Each muscle is subdivided into smaller bundles called fascicles, which are surrounded by a connective tissue covering called the perimysium. The number of fascicles and their size vary among muscles. Fascicles consist of many elongated structures called muscle fibers, each of which is surrounded by connective tissue called the endomysium. Skeletal muscles are syncytial or multinucleated structures, meaning there are no true cell boundaries within a skeletal muscle fiber.9

The sarcolemma of the muscle fiber is contained within the sarcolemma, which represents the cell membrane. Embedded throughout the sarcolemma are the contractile elements actin and myosin, which are arranged in parallel bundles called myofibrils. The thin, lighter-staining myofilaments are composed of actin, and the thicker, darker-staining myofilaments are composed of myosin. Each myofibril consists of regularly repeating units along the length of the myofibril, called sarcomeres (see Fig. 4.22B).9

Sarcomeres are the structural and functional units of cardiac and skeletal muscle. A sarcomere extends from one Z line to another Z line. Within the sarcomere are alternating light and dark bands. The central portion of the sarcomere contains the dark band (A band) consisting mainly of myosin filaments, with some overlap with actin filaments. Straddling the Z line, the lighter I band contains only actin filaments; therefore, it takes two sarcomeres to complete an I band. An H zone is found in the middle of the A band and represents the region where only myosin filaments are found. In the center of the H zone is a thin, dark band, the M band or M line, produced by linkages between the myosin filaments. Z lines consist of short elements that interconnect and provide the thin actin filaments from two adjoining sarcomeres with an anchoring point.

The sarcoplasmic reticulum, which is comparable to the smooth ER, is composed of longitudinal tubules that
run parallel to the muscle fiber and surround each myofibril (see Fig. 4.22D). This network ends in enlarged, saclike regions called the lateral sacs or terminal cisternae. These sacs store calcium that is released during muscle contraction. A binding protein called calsequestrin found in the terminal cisternae enables a high concentration of calcium ions to be sequestered in the cisternae. Concentration levels of calcium ions in the cisternae are 10,000 times higher than in the sarcoplasm.

A second system of tubules consists of the transverse or T tubules, which are extensions of the plasma membrane and run perpendicular to the muscle fiber. The hollow portion or lumen of the transverse tube is continuous with the extracellular fluid compartment. Action potentials, which are rapidly conducted over the surface of the muscle fiber, are in turn propagated by the T tubules into the sarcoplasmic reticulum. As the action potential moves through the lateral sacs, the sacs release calcium, initiating muscle contraction. The membrane of the sarcoplasmic reticulum also has an active transport mechanism for pumping calcium back into the reticulum. This prevents interactions between calcium ions and the actin and myosin myofilaments after cessation of a muscle contraction.

**Skeletal Muscle Contraction.** During muscle contraction, the thick myosin and thin actin filaments slide over each other, causing shortening of the muscle fiber, although the length of the individual thick and thin filaments remains unchanged (see Fig. 4.22C). The structures that produce the sliding of the filaments are the myosin heads that form cross-bridges with the thin actin filaments (Fig. 4.23). When activated by ATP, the cross-bridges swivel in a fixed arc, much like the oars of a boat, as they become attached to the actin filament. During contraction, each cross-bridge undergoes its own cycle of movement, forming a bridge attachment and releasing it, and moving to another site where the same sequence of movement occurs. This pulls the thin and thick filaments past each other.

Myosin is the chief constituent of the thick filament. It consists of a thin tail, which provides the structural backbone for the filament, and a globular head. Each globular head contains a binding site able to bind to a complementary site on the actin molecule. Besides the binding site for actin, each myosin head has a separate active site that catalyzes the breakdown of ATP to provide the energy needed to activate the myosin head so that it can form a cross-bridge with actin. After contraction, myosin also binds ATP, thus breaking the linkage between actin and myosin. Myosin molecules are bundled together side by side in the thick filaments such that one half have their heads toward one end of the filament and their tails toward the other end; the other half are arranged in the opposite manner.

The thin filaments are composed mainly of actin, a globular protein lined up in two rows that coil around each other to form a long helical strand. Associated with each actin filament are two regulatory proteins, tropomyosin and troponin (see Fig. 4.23A). *Tropomyosin*, which lies in grooves of the actin strand, provides the site for attachment of the globular heads of the myosin filament. In the noncontracted state, *troponin* covers the tropomyosin-binding sites and prevents formation of cross-bridges between the actin and myosin. During an action potential, calcium ions released from the sarcoplasmic reticulum diffuse to the adjacent myofibrils, where they bind to troponin. Binding of calcium to troponin uncovers the tropomyosin-binding sites such that the myosin heads can attach and form cross-bridges. Energy from ATP is used to break the actin and myosin cross-bridges, stopping the muscle contraction. After the linkage between actin and...
myosin is broken, the concentration of calcium around the myofibrils decreases as calcium is actively transported into the sarcoplasmic reticulum by a membrane pump that uses energy derived from ATP.

The basis of rigor mortis can be explained by the binding of actin and myosin. As the muscle begins to degenerate after death, the sarcoplasmic cisternae release their calcium ions, which enable the myosin heads to combine with their sites on the actin molecule. As ATP supplies diminish, no energy source is available to start the normal interaction between actin and myosin, and the muscle is in a state of rigor until further degeneration destroys the cross-bridges between actin and myosin.

**Smooth Muscle**

Smooth muscle is often called involuntary muscle because its activity arises spontaneously or through activity of the autonomic nervous system. Smooth muscle contractions are slower and more sustained than skeletal or cardiac muscle contractions.

**Organization and Structure.** Smooth muscle cells are spindle shaped and smaller than skeletal muscle fibers. Each smooth muscle cell has one centrally positioned nucleus. Z lines and M lines are not present in smooth muscle fibers, and cross-striations are absent because the bundles of filaments are not parallel but crisscross obliquely through the cell. Instead, the actin filaments are attached to structures called dense bodies (Fig. 4.24). Some dense bodies are attached to the cell membrane, and others are dispersed in the cell and linked together by structural proteins.

**FIGURE 4.23** - Molecular structure of the thin actin filament (A) and the thicker myosin filament (B) of striated muscle. The thin filament is a double-stranded helix of actin molecules with tropomyosin and troponin molecules lying along the grooves of the actin strands. (C) Sequence of events involved in sliding of adjacent actin and myosin filaments: (1) Cocking of the myosin head occurs as ATP is split to ADP, (2) cross-bridge attachment, (3) power stroke during which the myosin head bends as it moves the actin forward, and (4) cross-bridge detachment occurs as a new ATP attaches to the myosin head.

**FIGURE 4.24** - Structure of smooth muscle showing the dense bodies. In smooth muscle, the force of contraction is transmitted to the cell membrane by bundles of intermediate fibers.
The lack of Z lines and the regular overlapping of contractile elements provide a greater range of tension development. This is important in hollow organs that undergo changes in volume, with consequent changes in the length of the smooth muscle fibers in their walls. Even with the distention of a hollow organ, the smooth muscle fiber retains some ability to develop tension, whereas such distention would stretch skeletal muscle beyond the area where the thick and thin filaments overlap.

Smooth muscle is usually arranged in sheets or bundles. In hollow organs, such as the intestines, the bundles are organized into the two-layered muscularis externa consisting of an outer, longitudinal layer and an inner, circular layer. A thinner muscularis mucosae often lies between the muscularis externa and the endothelium. In blood vessels, the bundles are arranged circularly or helically around the vessel wall.

**Smooth Muscle Contraction.** As with cardiac and skeletal muscle, smooth muscle contraction is initiated by an increase in intracellular calcium. However, smooth muscle differs from skeletal muscle in the way its cross-bridges are formed. The sarcoplasmic reticulum of smooth muscle is less developed than in skeletal muscle, and no transverse tubules are present. Smooth muscle relies on the entrance of extracellular calcium and its release from the sarcoplasmic reticulum for muscle contraction. This dependence on movement of extracellular calcium across the cell membrane during muscle contraction is the basis for the action of calcium-blocking drugs used in the treatment of cardiovascular disease.

Smooth muscle also lacks troponin, the calcium-binding regulatory protein found in skeletal and cardiac muscle. Instead, it relies on another calcium-binding protein called calmodulin. The calcium–calmodulin complex binds to and activates the myosin-containing thick filaments, which interact with actin.

**Types of Smooth Muscle.** Smooth muscle may be divided into two broad categories according to the mode of activation: multiunit and single-unit smooth muscle. In multiunit smooth muscle, each unit operates almost independently of the others and is often innervated by a single nerve, such as occurs in skeletal muscle. It has little or no inherent activity and depends on the autonomic nervous system for its activation. This type of smooth muscle is found in the iris, in the walls of the vas deferens, and attached to hairs in the skin. The fibers in single-unit smooth muscle are in close contact with each other and can contract spontaneously without nerve or hormonal stimulation. Normally, most of the muscle fibers contract synchronously, hence the term single-unit smooth muscle. Some single-unit smooth muscle, such as that found in the gastrointestinal tract, is self-excitable. This is usually associated with a basic slow-wave rhythm transmitted from cell to cell by nexuses (i.e., gap junctions) formed by the fusion of adjacent cell membranes. The cause of this slow-wave activity is unknown. The intensity of contraction increases with the frequency of the action potential. Certain hormones, other agents, and local factors can modify smooth muscle activity by depolarizing or hyperpolarizing the membrane. Smooth muscle cells found in the uterus and small-diameter blood vessels are also single-unit smooth muscle.

**Nervous Tissue**

Nervous tissue is distributed throughout the body as an integrated communication system. Anatomically, the nervous system is divided into the CNS, which consists of the brain and spinal cord, and the PNS, which consists of nerve fibers and ganglia that exist outside the CNS. Nerve cells develop from the embryonic ectoderm. Nerve cells are highly differentiated and therefore incapable of regeneration in postnatal life.

Structurally, nervous tissue consists of two cell types: nerve cells or neurons and glial or supporting cells. Most nerve cells consist of three parts: the soma or cell body, dendrites, and the axon. The cytoplasm-filled dendrites, which are multiple elongated processes, receive and carry stimuli from the environment, from sensory epithelial cells, and from other neurons to the cell. The axon, which is a single cytoplasm-filled process, is specialized for generating and conducting nerve impulses away from the cell body to other nerve cells, muscle cells, and glandular cells.

Neurons can be classified as afferent and efferent neurons according to their function. Afferent or sensory neurons carry information toward the CNS; they are involved in the reception of sensory information from the external environment and from within the body. Efferent or motor neurons carry information away from the CNS; they are needed for control of muscle fibers and endocrine and exocrine glands.

Communication between neurons and effector organs, such as muscle cells, occurs at specialized structures called synapses. At the synapse, chemical messengers (i.e., neurotransmitters) alter the membrane potential to conduct impulses from one nerve to another or from a neuron to an effector cell. In addition, electrical synapses exist in which nerve cells are linked through gap junctions that permit the passage of ions from one cell to another.

Neuroglia (glia means "glue") are the cells that support neurons, form myelin, and have trophic and phagocytic functions. Four types of neuroglia are found in the CNS: astrocytes, oligodendrocytes, microglia, and ependymal cells. Astrocytes are the most abundant of the neuroglia. They have many long processes that surround blood vessels in the CNS. They provide structural support for the neurons, and their extensions form a sealed barrier that protects the CNS. The oligodendrocytes provide myelination of neuronal processes in the CNS. The microglia are phagocytic cells that represent the mononuclear phagocytic system in the nervous system. Ependymal cells line the cavities of the brain and spinal cord and are in contact with the cerebrospinal fluid. In the PNS, supporting cells consist of the Schwann and satellite cells. The Schwann cells provide myelination of the axons and dendrites, and the satellite cells enclose and protect the dorsal root ganglia and autonomic ganglion cells.
Extracellular Tissue Components

The discussion thus far has focused on the cellular components of the different tissue types. Within tissues, cells are held together by cell junctions; the space between cells is filled with an extracellular matrix; and adhesion molecules form intercellular contacts.

Extracellular Matrix

Tissues are not made up solely of cells. A large part of their volume is made up of an extracellular matrix. This matrix is composed of a variety of proteins and polysaccharides (i.e., a molecule made up of many sugars).6 These proteins and polysaccharides are secreted locally and are organized into a supporting meshwork in close association with the cells that produced them. The amount and composition of the matrix vary with the different tissues and their function. In bone, for example, the matrix is more plentiful than the cells that surround it; in the brain, the cells are much more abundant and the matrix is only a minor constituent.6

Two main classes of extracellular macromolecules make up the extracellular matrix. The first is composed of polysaccharide chains of a class called glycosaminoglycans (GAGs), which are usually found linked to protein as proteoglycans.10 The second type consists of the fibrous proteins (i.e., collagen and elastin) and the fibrous adhesive proteins (i.e., fibronectin and laminin) that are found in the basement membrane. Members of each of these two classes of extracellular macromolecules come in a variety of shapes and sizes.

The proteoglycan and GAG molecules in connective tissue form a highly hydrated, gel-like substance, or tissue gel, in which the fibrous proteins are embedded.10 The polysaccharide gel resists compressive forces, the collagen fibers strengthen and help organize the matrix, the rubber-like elastin adds resilience, and the adhesive proteins help cells attach to the appropriate part of the matrix. Polysaccharides in the tissue gel are highly hydrophilic, and they form gels even at low concentrations. They also accumulate a negative charge that attracts cations such as sodium, which are osmotically active, causing large amounts of water to be sucked into the matrix. This creates a swelling pressure, or turgor, that enables the matrix to withstand extensive compressive forces. This is in contrast to collagen, which resists stretching forces. For example, the cartilage matrix that lines the knee joint can support pressures of hundreds of atmospheres by this mechanism.

GAG and proteoglycan molecules in connective tissue usually constitute less than 10% by weight of fibrous tissue. Because they form a hydrated gel, the molecules fill most of the extracellular space, providing mechanical support to the tissues while ensuring rapid diffusion of water and electrolytes and the migration of cells. One GAG, hyaluronan or hyaluronic acid, is thought to play an important role as a space-filler during embryonic development. It creates a cell-free space into which cells subsequently migrate.10 When cell migration and organ development are complete, the excess hyaluronan is degraded by the enzyme hyaluronidase.

Hyaluronan is also important in directing the cell replacement that occurs during wound repair.10 Three types of fibers are found in the extracellular space: collagen, elastin, and reticular fibers. Collagen is the most common protein in the body. It is a tough, nonliving, white fiber that serves as the structural framework for skin, ligaments, tendons, and many other structures. Elastin acts like a rubber band; it can be stretched and then returns to its original form. Elastin fibers are abundant in structures subjected to frequent stretching, such as the aorta and some ligaments. Reticular fibers are extremely thin fibers that create a flexible network in organs subjected to changes in form or volume, such as the spleen, liver, uterus, or intestinal muscle layer.6

Adhesion Molecules

Important classes of extracellular macromolecules are the CAMs. CAMs can be cell-to-cell or cell-to-matrix adhesion molecules. There are four main classes of CAMs: cadherins, selectins, integrins, and the immunoglobulin (Ig) superfamily of proteins.10 Cadherins, selectins, and integrins all depend on extracellular calcium ions (or magnesium for some integrins) to function. The calcium-independent cell-to-cell adhesion molecules belong to the Ig superfamily of proteins.

Cadherins. Cadherins link parts of the internal cytoskeleton (actin and structures called catenins) with extracellular cadherins of an adjacent cell.10 This type of linkage is called homophilic, meaning that molecules on one cell bind to other molecules of the same type on adjacent cells. More than 40 different types of cadherins are known, and they are found in such intercellular junctions as the zonula and macula adherens.10

Selectins. Selectins bind carbohydrates present on the ligands of an adjacent cell in a heterophilic type of interaction. In heterophilic interactions, the molecules on one cell bind to molecules of a different type on adjacent cells. Selectins are found on activated endothelial cells of blood vessels, on leukocytes, and on platelets. They, together with integrins and Igs, participate in leukocyte movement through the endothelial lining of blood vessels during inflammation.10

Integrins. Integrins usually assist in attaching epithelial cells to the underlying basement membrane.10 Unlike other CAMs, they are heterodimers consisting of α and β subunits. Extracellularly, they are attached to fibronectin and laminin, the two major components of the basement membrane. Like the cadherins, their intracellular portion is linked to actin. One group of integrins is associated with hemidesmosomes, whereas others are associated with the surface of white blood cells, macrophages, and platelets. Integrins usually have a weak affinity for their ligands unless they are associated with cellular focal contacts and hemidesmosomes. This allows some movement between cells except where a firm attachment is required to attach epithelial cells to the underlying connective tissue.
Certain integrins play an important role in allowing white blood cells to pass through the vessel wall, a process called transmigration. Persons affected with leukocyte adhesion deficiency are unable to synthesize appropriate integrin molecules. As a result, they experience repeated bacterial infections because their white blood cells are unable to transmigrate through vessel walls.

Ig Superfamily. The Ig superfamily proteins consist of groups of one or more Ig-like adhesion proteins that are structurally similar to antibody molecules. The best-studied example of Ig superfamily proteins is the neural cell adhesion molecules (NCAMs), which are expressed in a variety of cells, including most nerve cells. All are calcium ion independent but, unlike other CAMs, they may participate in homophilic or heterophilic interactions. Heterophilic attachments are to other members of the superfamily such as intracellular adhesion molecules (ICAMs). During early development of the CNS, cells at the roof of the neural tube express high levels of NCAM on their cell surface and are unable to move because of intercellular adhesions. Future neural crest cells lose their NCAM and begin migrating to various areas of the body. Members of the Ig superfamily also play a role in the homing process of leukocytes during inflammation.

IN SUMMARY

Body cells are organized into four basic tissue types: epithelial, connective, muscle, and nervous. The epithelium covers and lines the body surfaces and forms the functional components of glandular structures. Epithelial tissue is classified into three types according to the shape of the cells and the number of layers that are present: simple, stratified, and pseudostratified. The cells in epithelial tissue are held together by three types of intercellular junctions: tight, adhering, and gap. They are attached to the underlying tissue by hemidesmosomes.

Connective tissue supports and connects body structures; it forms the bones and skeletal system, joint structures, blood cells, and intercellular substances. Connective tissue proper can be divided into four types: loose or areolar, which fills body spaces and is characterized by an abundance of ground substance; adipose, which stores fat; reticular, which forms the architectural framework in many structures of the body; and dense, regular and irregular, which forms structures such as tendons and ligaments (regular) and the dermis of the skin (irregular).

Muscle tissue is a specialized tissue designed for contractility. Three types of muscle tissue exist: skeletal, cardiac, and smooth. Actin and myosin filaments interact to produce muscle shortening, a process activated by the presence of calcium. In skeletal muscle, calcium is released from the sarcoplasmic reticulum in response to an action potential. Smooth muscle is often called involuntary muscle because it contracts spontaneously or through activity of the autonomic nervous system. It differs from skeletal muscle in that its sarcoplasmic reticulum is less defined and it depends on the entry of extracellular calcium ions for muscle contraction.

Nervous tissue is designed for communication purposes and includes the neurons, the supporting neural structures, and the ependymal cells that line the ventricles of the brain and the spinal canal.

The extracellular matrix is made up of a variety of proteins and polysaccharides. These proteins and polysaccharides are secreted locally and are organized into a supporting meshwork in close association with the cells that produced them. The amount and composition of matrix vary with the different tissues and their function. Extracellular fibers include collagen fibers, which comprise tendons and ligaments; elastic fibers, found in large arteries and some ligaments; and thin reticular fibers, which are plentiful in organs that are subject to a change in volume (e.g., spleen and liver). Important classes of extracellular macromolecules are the adhesion molecules that maintain intercellular contacts. There are three classes of adhesion molecules that depend on extracellular calcium to function in cell adhesion: cadherins, which link parts of the internal cytoskeleton with the extracellular cadherins of an adjacent cell; selectins, which bind carbohydrates present on the ligands of adjacent cells; and integrins (some of which are magnesium dependent), which assist in attaching epithelial cells to the underlying basement membrane. The Ig superfamily proteins are calcium-independent adhesion molecules that bind cells, such as those of the nervous system, together.

REVIEW EXERCISES

1. Tattoos consist of pigments that have been injected into the skin.
   A. Explain what happens to the dye once it has been injected and why it does not eventually wash away.
2. People who drink sufficient amounts of alcohol display rapid changes in CNS function, including both motor and behavioral changes, and the odor of alcohol can be detected on their breath.
   A. Use the concepts related to the lipid bilayer structure of the cell membrane to explain these observations.
3. The absorption of glucose from the intestine involves a cotransport mechanism in which the active primary transport of sodium ions is used to provide for the secondary transport of glucose.
   A. Hypothesize how this information might be used to design an oral rehydration solution for someone who is suffering from diarrhea.

When confronted with stresses that endanger its normal structure and function, the cell undergoes adaptive changes that permit survival and maintenance of function. It is only when the stress is overwhelming or adaptation is ineffective that cell injury and death occur. This chapter focuses on cellular adaptation, injury, and death.

Cells adapt to changes in the internal environment, just as the total organism adapts to changes in the external environment. Cells may adapt by undergoing changes in size, number, and type. These changes, occurring singly or in combination, may lead to

- Atrophy
- Hypertrophy
- Hyperplasia
- Metaplasia
- Dysplasia

Adaptive cellular responses also include intracellular accumulations and storage of products in abnormal amounts.1

There are numerous molecular mechanisms mediating cellular adaptation, including factors produced by other cells.
or by the cells themselves. These mechanisms depend largely on signals transmitted by chemical messengers that exert their effects by altering gene function. In general, the genes expressed in all cells fall into two categories:

- Operating genes that are necessary for normal function of a cell
- Genes that determine the differentiating characteristics of a particular cell type

In many adaptive cellular responses, the expression of the differentiation genes is altered, whereas that of the operating genes remains unaffected. Thus, a cell is able to change size or form without compromising its normal function. Once the stimulus for adaptation is removed, the effect on expression of the differentiating genes is removed and the cell resumes its previous state of specialized function. Whether adaptive cellular changes are normal or abnormal depends on whether the response was mediated by an appropriate stimulus. Normal adaptive responses occur in response to need and an appropriate stimulus. After the need has been removed, the adaptive response ceases.

### KEY POINTS

#### CELLULAR ADAPTATIONS

- Cells are able to adapt to increased work demands or threats to survival by changing their size (atrophy and hypertrophy), number (hyperplasia), and form (metaplasia).
- Normal cellular adaptation occurs in response to an appropriate stimulus and ceases once the need for adaptation has ceased.

### Atrophy

When confronted with a decrease in work demands or adverse environmental conditions, most cells are able to revert to a smaller size and a lower and more efficient level of functioning that is compatible with survival. This decrease in cell size is called atrophy and is illustrated in Figure 5.1 regarding atrophy of the endometrium. Cells that are atrophied reduce their oxygen consumption and other cellular functions by decreasing the number and size of their organelles and other structures. There are fewer mitochondria, myofilaments, and endoplasmic reticulum structures. When a sufficient number of cells are involved, the entire tissue or muscle atrophies.

Cell size, particularly in muscle tissue, is related to workload. As the workload of a cell declines, oxygen consumption and protein synthesis decrease. Furthermore, proper muscle mass is maintained by sufficient levels of insulin and insulin-like growth factor-1 (IGF-1). When insulin and IGF-1 levels are low or catabolic signals are present, muscle atrophy occurs by mechanisms that include reduced synthetic processes, increased proteolysis by the ubiquitin–proteasome system, and apoptosis or programmed cell death. In the ubiquitin–proteasome system, intracellular proteins destined for destruction are covalently bonded to a small protein called ubiquitin and then degraded by small cytoplasmic organelles called proteasomes.

The general causes of atrophy can be grouped into five categories:

1. Disuse
2. Denervation
3. Loss of endocrine stimulation
4. Inadequate nutrition
5. Ischemia or decreased blood flow

Disuse atrophy occurs when there is a reduction in skeletal muscle use. An extreme example of disuse atrophy is seen...
in the muscles of extremities that have been encased in plaster casts. Because atrophy is adaptive and reversible, muscle size is restored after the cast is removed and muscle use is resumed. Denervation atrophy is a form of disuse atrophy that occurs in the muscles of paralyzed limbs. Lack of endocrine stimulation produces a form of disuse atrophy. In women, the loss of estrogen stimulation during menopause results in atrophic changes in the reproductive organs. With malnutrition and decreased blood flow, cells decrease their size and energy requirements as a means of survival.

**Hypertrophy**

Hypertrophy represents an increase in cell size and with it an increase in the amount of functioning tissue mass (Fig. 5.2). It results from an increased workload imposed on an organ or body part and is commonly seen in cardiac and skeletal muscle tissue, which cannot adapt to an increase in workload through mitotic division and formation of more cells. Hypertrophy involves an increase in the functional components of the cell that allows it to achieve equilibrium between demand and functional capacity. For example, as muscle cells hypertrophy, additional actin and myosin filaments, cell enzymes, and adenosine triphosphate (ATP) are synthesized.

Hypertrophy may occur as the result of normal physiologic or abnormal pathologic conditions. The increase in muscle mass associated with exercise is an example of physiologic hypertrophy. Pathologic hypertrophy occurs as the result of disease conditions and may be adaptive or compensatory. Examples of adaptive hypertrophy are the thickening of the urinary bladder from long-continued obstruction of urinary outflow and the myocardial hypertrophy that results from valvular heart disease or hypertension. Compensatory hypertrophy is the enlargement of a remaining organ or tissue after a portion has been surgically removed or rendered inactive. For instance, if one kidney is removed, the remaining kidney enlarges to compensate for the loss.

The initiating signals for hypertrophy appear to be complex and related to ATP depletion, mechanical forces such as stretching of the muscle fibers, activation of cell degradation products, and hormonal factors. In the case of the heart, initiating signals can be divided into two broad categories:

1. **Biomechanical and stretch-sensitive mechanisms**
2. **Neurohumoral mechanisms that are associated with the release of hormones, growth factors, cytokines, and chemokines**

Internal stretch-sensitive receptors for the biochemical signals and an array of membrane-bound receptors for the specific neurohumoral ligands, such as IGF-1 and epidermal growth factor (EGF), activate specific signal transduction pathways. These pathways control myocardial growth by altering gene expression to increase protein synthesis and reduce protein degradation, thereby causing hypertrophic enlargement of the heart. A limit is eventually reached beyond which further enlargement of the tissue mass can no longer compensate for the increased work demands. The limiting factors for continued hypertrophy might be related to limitations in blood flow. In hypertension, for example, the increased workload required to pump blood against an elevated arterial pressure in the aorta results in a progressive increase in left ventricular muscle mass and need for coronary blood flow.

There continues to be interest in the signaling pathways that control the arrangement of contractile elements in myocardial hypertrophy. Research suggests that certain signal molecules can alter gene expression controlling the size and assembly of the contractile proteins in hypertrophied myocardial cells. For example, the hypertrophied myocardial cells of well-trained athletes have proportional increases in width and length. This is in contrast to the hypertrophy that develops in dilated cardiomyopathy, in which the hypertrophied cells have a relatively greater increase in length than width. In pressure overload, as occurs with hypertension, the hypertrophied cells have greater width than length. It is anticipated that further elucidation of the signal pathways that determine the adaptive and nonadaptive features of cardiac hypertrophy will lead to new targets for treatment.

**Hyperplasia**

Hyperplasia refers to an increase in the number of cells in an organ or tissue. It occurs in tissues with cells that are capable of mitotic division, such as the epidermis, intestinal epithelium, and glandular tissue. Certain cells, such as neurons, rarely divide and therefore have little capacity, if any, for hyperplastic growth. There is evidence that hyperplasia involves activation of genes controlling cell proliferation and the presence of intracellular messengers that control cell replication and growth. As with other normal adaptive cellular responses, hyperplasia is a controlled process that occurs in response to an appropriate stimulus and ceases after the stimulus has been removed.
The stimuli that induce hyperplasia may be physiologic or nonphysiologic. There are two common types of physiologic hyperplasia: hormonal and compensatory. Breast and uterine enlargements during pregnancy are examples of a physiologic hyperplasia that results from estrogen stimulation. The regeneration of the liver that occurs after partial heptectomy (i.e., partial removal of the liver) is an example of compensatory hyperplasia. Hyperplasia is also an important response of connective tissue in wound healing, during which proliferating fibroblasts and blood vessels contribute to wound repair. Although hypertrophy and hyperplasia are two distinct processes, they may occur together and are often triggered by the same mechanism. For example, the pregnant uterus undergoes both hypertrophy and hyperplasia as the result of estrogen stimulation.

Most forms of nonphysiologic hyperplasia are due to excessive hormonal stimulation or the effects of growth factors on target tissues. The public seems to appreciate that a laboratory finding including the term hyperplasia generally is something to take seriously. For example, excessive estrogen production can cause endometrial hyperplasia and abnormal menstrual bleeding. Endometrial hyperplasia is considered a high risk for developing endometrial cancer and is a risk factor for developing esophageal adenocarcinoma. Women with atypical hyperplasia of the breast are also monitored carefully. Skin warts are another example of hyperplasia caused by growth factors produced by certain viruses, such as the papillomaviruses.

**Metaplasia**

Metaplasia represents a reversible change in which one adult cell type (epithelial or mesenchymal) is replaced by another adult cell type. Metaplasia is thought to involve the reprogramming of undifferentiated stem cells that are present in the tissue undergoing the metaplastic changes.

Metaplasia usually occurs in response to chronic irritation and inflammation and allows for substitution of cells that are better able to survive under circumstances in which a more fragile cell type might succumb. However, the conversion of cell types never oversteps the boundaries of the primary tissue type (e.g., one type of epithelial cell may be converted to another type of epithelial cell, but not to a connective tissue cell). An example of metaplasia is the adaptive substitution of stratified squamous epithelial cells for the ciliated columnar epithelial cells in the trachea and large airways of a habitual cigarette smoker. Barrett esophagus is a premalignant condition that occurs in the esophagus of people with chronic gastroesophageal reflux disease (GERD). It is characterized by normal squamous epithelium in the lower esophagus transforming into columnar-lined epithelium. Barrett esophagus is the primary risk factor for developing esophageal adenocarcinoma.

**Dysplasia**

Dysplasia is characterized by deranged cell growth of a specific tissue that results in cells that vary in size, shape, and organization. Minor degrees of dysplasia are associated with chronic irritation or inflammation. The pattern is most frequently encountered in areas of metaplastic squamous epithelium of the respiratory tract and uterine cervix. Although dysplasia is abnormal, it is adaptive in that it is potentially reversible after the irritating cause has been removed. Dysplasia is strongly implicated as a precursor of cancer. In cancers of the respiratory tract and the uterine cervix, dysplastic changes have been found adjacent to the foci of cancerous transformation. Through the use of the Papanicolaou (Pap) smear, it has been documented that cancer of the uterine cervix develops in a series of incremental epithelial changes ranging from severe dysplasia to invasive cancer. However, dysplasia is an adaptive process and as such does not necessarily lead to cancer.

Preterm babies who are ventilated for long periods of time due to their prematurity and lack of surfactant, and term infants who require intubation and ventilated oxygen in the first month of life, often develop bronchopulmonary dysplasia (BPD). In fact there are more preterm babies surviving today, so more BPD is evident. Approximately 20% of infants born at less than 30 weeks’ gestation and weighing less than 1500 g develop BPD. Although there has been some excellent therapy that has decreased some of the negative lung disease experienced by infants with BPD, many infants who develop BPD experience the long-term effects of alveolar destruction the rest of their lives.

**Intracellular Accumulations**

Intracellular accumulations represent the buildup of substances that cells cannot immediately use or eliminate. The substances may accumulate in the cytoplasm (frequently in the lysosomes) or in the nucleus. In some cases the accumulation may be an abnormal substance that the cell has produced, and in other cases the cell may be storing exogenous materials or products of pathologic processes occurring elsewhere in the body. An example would be the accumulation of beta amyloid fragments, which progress to a skeletal muscle disorder called myositis.

These substances may accumulate transiently or permanently, and they may be harmless or, in some cases, toxic. These substances can be grouped into three categories:

1. Normal body substances, such as lipids, proteins, carbohydrates, melanin, and bilirubin, that are present in abnormally large amounts
2. Abnormal endogenous products, such as those resulting from inborn errors of metabolism
3. Exogenous products, such as environmental agents and pigments, that cannot be broken down by the cell

The accumulation of normal cellular constituents occurs when a substance is produced at a rate that exceeds its metabolism or removal. An example of this type of process is fatty changes in the liver due to intracellular accumulation of triglycerides. Liver cells normally contain some fat, which is either oxidized and used in the cell by the cell.
for energy or converted to triglycerides. This fat is derived from free fatty acids released from adipose tissue. Abnormal accumulation occurs when the delivery of free fatty acids to the liver is increased, as in starvation and diabetes mellitus, or when the intrahepatic metabolism of lipids is disturbed, as in alcoholism.

Intracellular accumulation can result from genetic disorders that disrupt the metabolism of selected substances. A normal enzyme may be replaced with an abnormal one, resulting in the formation of a substance that cannot be used or eliminated from the cell, or an enzyme may be missing, so that an intermediate product accumulates in the cell. For example, there are at least 10 genetic disorders that affect glycogen metabolism, most of which lead to the accumulation of intracellular glycogen stores. In the most common form of this disorder, von Gierke disease, large amounts of glycogen accumulate in the liver and kidneys because of a deficiency of the enzyme glucose-6-phosphatase. Without this enzyme, glycogen cannot be broken down to form glucose. The disorder leads not only to an accumulation of glycogen but also to a reduction in blood glucose levels. In Tay-Sachs disease, another genetic disorder, abnormal lipids accumulate in the brain and other tissues, causing motor and mental deterioration beginning at approximately 6 months of age, followed by death at 2 to 5 years of age. In a similar manner, other enzyme defects lead to the accumulation of other substances.

Pigments are colored substances that may accumulate in cells. They can be endogenous (i.e., arising from within the body) or exogenous (i.e., arising from outside the body). Jaundice, also called icterus, is characterized by a yellow discoloration of tissue due to the retention of bilirubin, an endogenous bile pigment. This condition may result from increased bilirubin production from red blood cell destruction, obstruction of bile passage into the intestine, or toxic diseases that affect the liver’s ability to remove bilirubin from the blood. Lipofuscin is a yellow-brown pigment that results from the accumulation of the indigestible residues produced during normal turnover of cell structures (Fig. 5.3). The accumulation of lipofuscin increases with age, and it is sometimes referred to as the wear-and-tear pigment. It is more common in heart, nerve, and liver cells than other tissues and is seen more often in conditions associated with atrophy of an organ.

One of the most common exogenous pigments is carbon in the form of coal dust. In coal miners or people exposed to heavily polluted environments, the accumulation of carbon dust blackens the lung tissue and may cause serious lung disease. The formation of a blue lead line along the margins of the gum is one of the diagnostic features of lead poisoning. Tattoos are the result of insoluble pigments introduced into the skin, where they are engulfed by macrophages and persist for a lifetime.

The significance of intracellular accumulations depends on the cause and severity of the condition. Many accumulations, such as lipofuscin and mild fatty change, have no effect on cell function. Some conditions, such as the hyperbilirubinemia that causes jaundice, are reversible. Other disorders, such as glycogen storage diseases, produce accumulations that result in organ dysfunction and other alterations in physiologic function.

**Pathologic Calcifications**

Pathologic calcification involves the abnormal tissue deposition of calcium salts, together with smaller amounts of iron, magnesium, and other minerals. It is known as dystrophic calcification when it occurs in dead or dying tissue and as metastatic calcification when it occurs in normal tissue.

**Dystrophic Calcification**

Dystrophic calcification represents the macroscopic deposition of calcium salts in injured tissue. It is often visible to the naked eye as deposits that range from gritty, sandlike grains to firm, hard rock material. The pathogenesis of dystrophic calcification involves the intracellular or extracellular formation of crystalline calcium phosphate. The components of the calcium deposits are derived from the bodies of dead or dying cells as well as from the circulation and interstitial fluid.

Dystrophic calcification is commonly seen in atheromatous lesions of advanced atherosclerosis, areas of injury in the aorta and large blood vessels, and damaged heart valves. Although the presence of calcification may only indicate the presence of previous cell injury, as in healed tuberculosis lesions, it is also a frequent cause of organ dysfunction. For example, calcification of the aortic valve is a frequent cause of aortic stenosis in older adults (Fig. 5.4).

**Metastatic Calcification**

In contrast to dystrophic calcification, which occurs in injured tissues, metastatic calcification occurs in normal tissues as the result of increased serum calcium levels (hypercalcemia). Almost any condition that increases the serum calcium level can lead to calcification in inappropriate sites such as the lung, renal tubules, and blood vessels. The major causes of hypercalcemia are hyperparathyroidism, either primary or secondary to phosphate retention in renal failure; increased mobilization of calcium from bone as in Paget disease, cancer with metastatic bone lesions, or immobilization; and vitamin D intoxication.

---

**FIGURE 5.3** Accumulation of intracellular lipofuscin. A photomicrograph of the liver of an 80-year-old man shows golden cytoplasmic granules, which represent lysosomal storage of lipofuscin. (From Rubin R., Strayer D. (2012). Rubin’s pathology: Clinicopathologic foundations of medicine (6 ed., p. 121), Philadelphia, PA: Lippincott Williams & Wilkins.)
Pathologic calcification involves the abnormal tissue deposition of calcium salts. Dystrophic calcification occurs in dead or dying tissue. Although the presence of dystrophic calcification may only indicate the presence of previous cell injury, it is also a frequent cause of organ dysfunction (e.g., when it affects the heart valves). Metastatic calcification occurs in normal tissues as the result of elevated serum calcium levels. Almost any condition that increases the serum calcium level can lead to calcification in inappropriate sites such as the lung, renal tubules, and blood vessels.

**CELL INJURY AND DEATH**

After completing this section of the chapter, you should be able to meet the following objectives:

- Describe the mechanisms whereby physical agents such as blunt trauma, electrical forces, and extremes of temperature produce cell injury.
- Differentiate between the effects of ionizing and non-ionizing radiation in terms of their ability to cause cell injury.
- State the mechanisms and manifestations of cell injury associated with lead poisoning.
- Relate free radical formation and oxidative stress to cell injury and death.

Cells can be injured in many ways. The extent to which any injurious agent can cause cell injury and death depends in large measure on the intensity and duration of the injury and the type of cell that is involved. Cell injury is usually reversible up to a certain point, after which irreversible cell injury and death occur. Whether a specific stress causes irreversible or reversible cell injury depends on the severity of the insult and on variables such as blood supply, nutritional status, and regenerative capacity. Cell injury and death are ongoing processes, and in the healthy state, they are balanced by cell renewal.
CAUSES OF CELL INJURY

Cell damage can occur in many ways. For purposes of discussion, the ways by which cells are injured have been grouped into five categories:

1. Injury from physical agents
2. Radiation injury
3. Chemical injury
4. Injury from biologic agents
5. Injury from nutritional imbalances

INJURY FROM PHYSICAL AGENTS

Physical agents responsible for cell and tissue injury include mechanical forces, extremes of temperature, and electrical forces. They are common causes of injuries due to environmental exposure, occupational and transportation accidents, and physical violence and assault.

MECHANICAL FORCES. Injury or trauma due to mechanical forces occurs as the result of body impact with another object. The body or the mass can be in motion or, as sometimes happens, both can be in motion at the time of impact. These types of injuries split and tear tissue, fracture bones, injure blood vessels, and disrupt blood flow.

EXTREMES OF TEMPERATURE. Extremes of heat and cold cause damage to the cell, its organelles, and its enzyme systems. Exposure to low-intensity heat (43°C to 46°C), such as occurs with partial-thickness burns and severe heat stroke, causes cell injury by inducing vascular injury, accelerating cell metabolism, inactivating temperature-sensitive enzymes, and disrupting the cell membrane. With more intense heat, coagulation of blood vessels and tissue proteins occurs. Exposure to cold increases blood viscosity and induces vasoconstriction by direct action on blood vessels and through reflex activity of the sympathetic nervous system. The resultant decrease in blood flow may lead to hypoxic tissue injury, depending on the degree and duration of cold exposure. Injury from freezing probably results from a combination of ice crystal formation and vasoconstriction. The decreased blood flow leads to capillary stasis and arteriolar and capillary thrombosis. Edema results from increased capillary permeability.

ELECTRICAL INJURIES. Electrical injuries can affect the body through extensive tissue injury and disruption of neural and cardiac impulses. Voltage, type of current, amperage, pathway of the current, resistance of the tissue, and interval of exposure determine the effect of electricity on the body.15

Alternating current (AC) is usually more dangerous than direct current (DC) because it causes violent muscle contractions, preventing the person from releasing the electrical source and sometimes resulting in fractures and dislocations. In electrical injuries, the body acts as a conductor of the electrical current.15 The current enters the body from an electrical source, such as an exposed wire, and passes through the body and exits to another conductor, such as the moisture on the ground or a piece of metal the person is holding. The pathway that a current takes is critical because the electrical energy disrupts impulses in excitable tissues. Current flow through the brain may interrupt impulses from respiratory centers in the brain stem, and current flow through the chest may cause fatal cardiac arrhythmias.

The resistance to the flow of current in electrical circuits transforms electrical energy into heat. This is why the elements in electrical heating devices are made of highly resistive metals. Much of the tissue damage produced by electrical injuries is caused by heat production in tissues that have the highest electrical resistance. Resistance to electrical current varies from the greatest to the least in bone, fat, tendons, skin, muscles, blood, and nerves. The most severe tissue injury usually occurs at the skin sites where the current enters and leaves the body (Fig. 5.5). After electricity has penetrated the skin, it passes rapidly through the body along the lines of least resistance—through body fluids and nerves. Degeneration of vessel walls may occur, and thrombi may form as current flows along the blood vessels. This can cause extensive muscle and deep tissue injury. Thick, dry skin is more resistant to the flow of electricity than thin, wet skin. It is generally believed that the greater the skin resistance, the greater is the amount of local skin burn, and the less the resistance, the greater are the deep and systemic effects.

RADIATION INJURY

Electromagnetic radiation comprises a wide spectrum of wave-propagated energy, ranging from ionizing gamma rays to radiofrequency waves (Fig. 5.6). A photon is a particle of radiation energy. Radiation energy above the ultraviolet (UV) range is called ionizing radiation because the photons have enough energy to knock electrons off atoms and molecules. Nonionizing radiation refers to radiation energy at frequencies below those of visible light. UV radiation represents the portion of the
Ionizing Radiation. Ionizing radiation impacts cells by causing ionization of molecules and atoms in the cell. This is accomplished by releasing free radicals that destroy cells and by directly hitting the target molecules in the cell. It can immediately kill cells, interrupt cell replication, or cause a variety of genetic mutations, which may or may not be lethal. Most radiation injury is caused by localized irradiation that is used in the treatment of cancer. Except for unusual circumstances such as the use of high-dose irradiation that precedes bone marrow transplantation, exposure to whole-body irradiation is rare.

The injurious effects of ionizing radiation vary with the dose, dose rate (a single dose can cause greater injury than divided or fractionated doses), and the differential sensitivity of the exposed tissue to radiation injury. Because of the effect on deoxyribonucleic acid (DNA) synthesis and interference with mitosis, rapidly dividing cells of the bone marrow and intestine are much more vulnerable to radiation injury than tissues such as bone and skeletal muscle. Over time, occupational and accidental exposure to ionizing radiation can result in increased risk for the development of various types of cancers, including skin cancers, leukemia, osteogenic sarcomas, and lung cancer. This is especially true when the person is exposed to radiation during childhood.

Many of the clinical manifestations of radiation injury result from acute cell injury, dose-dependent changes in the blood vessels that supply the irradiated tissues, and fibrotic tissue replacement. The cell’s initial response to radiation injury involves swelling, disruption of the mitochondria and other organelles, alterations in the cell membrane, and marked changes in the nucleus. The endothelial cells in blood vessels are particularly sensitive to irradiation. During the immediate postirradiation period, only vessel dilatation is apparent (e.g., the initial erythema of the skin after radiation therapy). Later or with higher levels of radiation, destructive changes occur in small blood vessels such as the capillaries and venules. Acute reversible necrosis is represented by such disorders as radiation cystitis, dermatitis, and diarrhea from enteritis. More persistent damage can be attributed to acute necrosis of tissue cells that are not capable of regeneration and chronic ischemia. Chronic effects of radiation damage are characterized by fibrosis and scarring of tissues and organs in the irradiated area (e.g., interstitial fibrosis of the heart and lungs after irradiation of the chest). Because the radiation delivered in radiation therapy inevitably travels through the skin, radiation dermatitis is common. There may be necrosis of the skin, impaired wound healing, and chronic radiation dermatitis.

Ultraviolet Radiation. Ultraviolet radiation causes sunburn and increases the risk of skin cancers. The degree of risk depends on the type of UV rays, the intensity of exposure, and the amount of protective melanin pigment in the skin. Skin damage produced by UV radiation is thought to be caused by reactive oxygen species (ROS) and by damage to melanin-producing processes in the skin. UV radiation also damages DNA, resulting in the formation of pyrimidine dimers (i.e., the insertion of two identical pyrimidine bases into replicating DNA instead of one). Other forms of DNA damage include the production of single-stranded breaks and formation of DNA–protein cross-links. Normally errors that occur during DNA replication are repaired by enzymes that remove the faulty section of DNA and repair the damage. The importance of DNA repair in protecting against UV radiation injury is evidenced by the vulnerability of people who lack the enzymes needed to repair UV-induced DNA damage. In a genetic disorder called xeroderma pigmentosum, an enzyme needed to repair sunlight-induced DNA damage is lacking. This autosomal recessive disorder is characterized by extreme photosensitivity and an increased risk of skin cancer in sun-exposed skin.

Nonionizing Radiation. Nonionizing radiation includes infrared light, ultrasound, microwaves, and laser energy. Unlike ionizing radiation, which can directly break chemical bonds, nonionizing radiation exerts its effects by causing vibration and rotation of atoms and molecules. All of
this vibrational and rotational energy is eventually converted to thermal energy. Low-frequency nonionizing radiation is used widely in radar, television, industrial operations (e.g., heating, welding, melting of metals, processing of wood and plastic), household appliances (e.g., microwave ovens), and medical applications (e.g., diathermy). Isolated cases of skin burns and thermal injury to deeper tissues have occurred in industrial settings and from improperly used household microwave ovens. Injury from these sources is mainly thermal and, because of the deep penetration of the infrared or microwave rays, tends to involve dermal and subcutaneous tissue injury.

Chemical Injury

Chemicals capable of damaging cells are everywhere around us. Air and water pollution contains chemicals capable of tissue injury, as does tobacco smoke and some processed or preserved foods. Some of the most damaging chemicals exist in our environment, including gases such as carbon monoxide, insecticides, and trace metals such as lead.

Chemical agents can injure the cell membrane and other cell structures, block enzymatic pathways, coagulate cell proteins, and disrupt the osmotic and ionic balance of the cell. Corrosive substances such as strong acids and bases destroy cells as the substances come into contact with the body. Other chemicals may injure cells in the process of metabolism or elimination. Carbon tetrachloride (CCl₄), for example, causes little damage until it is metabolized by liver enzymes to a highly reactive free radical (CCl₃•). Carbon tetrachloride is extremely toxic to liver cells.²⁰

Drugs. Many drugs—alcohol, prescription drugs, over-the-counter drugs, and street drugs—are capable of directly or indirectly damaging tissues. Ethyl alcohol can harm the gastric mucosa, liver, developing fetus, and other organs. Antineoplastic and immunosuppressant drugs can directly injure cells. Other drugs produce metabolic end products that are toxic to cells. Acetaminophen, a commonly used over-the-counter analgesic drug, is detoxified in the liver, where small amounts of the drug are converted to a highly toxic metabolite. This metabolite is detoxified by a metabolic pathway that uses a substance (i.e., glutathione) normally present in the liver. When large amounts of the drug are ingested, this pathway becomes overwhelmed and toxic metabolites accumulate, causing massive liver necrosis.

Lead Toxicity. Lead is a particularly toxic metal. Small amounts accumulate to reach toxic levels. There are innumerable sources of lead in the environment, including flaking paint, lead-contaminated dust and soil, lead-contaminated root vegetables, lead water pipes or soldered joints, pottery glazes, newsprint, and toys made in foreign countries. Adults often encounter lead through occupational exposure. Children are exposed to lead through ingestion of peeling lead paint, by breathing dust from lead paint, or from playing in contaminated soil. There has been a decline in blood lead levels of both adults and children since the removal of lead from gasoline and from soldered food cans.²¹ High blood lead levels continue to be a problem, however, particularly among children. In the United States alone, there are approximately 250,000 children between 1 and 5 years of age who have lead levels greater than 10 μg/mL.²² The prevalence of elevated blood lead levels was higher for children living in more urbanized areas. By race or ethnicity, non-Hispanic Black children residing in central cities with a population of 1 million or more had the highest proportion of elevated blood lead levels.

Lead is absorbed through the gastrointestinal tract or the lungs into the blood. A deficiency in calcium, iron, or zinc increases lead absorption. In children, most lead is absorbed through the lungs. Although children may have the same or a lower intake of lead, the absorption in infants and children is greater; thus, they are more vulnerable to lead toxicity.²² Lead crosses the placenta, exposing the fetus to levels of lead that are comparable with those of the mother. Lead is stored in bone and eliminated by the kidneys. Although the half-life of lead is hours to days, bone deposits serve as a repository from which blood levels are maintained. In a sense, bone protects other tissues, but the slow turnover maintains blood levels for months to years.

The toxicity of lead is related to its multiple biochemical effects. It has the ability to inactivate enzymes, compete with calcium for incorporation into bone, and interfere with nerve transmission and brain development. The major targets of lead toxicity are the red blood cells, the gastrointestinal tract, the kidneys, and the nervous system.

Anemia is a cardinal sign of lead toxicity. Lead competes with the enzymes required for hemoglobin synthesis and with the membrane-associated enzymes that prevent hemolysis of red blood cells. The resulting red cells are coarsely stippled and hypochromic, resembling those seen in iron-deficiency anemia. The life span of the red cell is also decreased. The gastrointestinal tract is the main source of symptoms in the adult. This is characterized by “lead colic,” a severe and poorly localized form of acute abdominal pain. A lead line formed by precipitated lead sulfite may appear along the gingival margins. The lead line is seldom seen in children. The kidneys are the major route for excretion of lead. Lead can cause diffuse kidney damage, eventually leading to renal failure. Even without overt signs of kidney damage, lead toxicity leads to hypertension.

In the nervous system, lead toxicity is characterized by demyelination of cerebral and cerebellar white matter and death of cortical cells. When this occurs in early childhood, it can affect neurobehavioral development and result in lower IQ levels and poorer classroom performance.¹¹ Peripheral demyelinating neuropathy may occur in adults. The most serious manifestation of lead poisoning is acute encephalopathy. It is manifested by persistent vomiting, ataxia, seizures, papilledema, impaired consciousness, and coma. Acute encephalopathy may manifest suddenly, or it may be preceded by other signs of lead toxicity such as behavioral changes or abdominal complaints.
Because of the long-term neurobehavioral and cognitive deficits that occur in children with even moderately elevated lead levels, the Centers for Disease Control and Prevention have issued recommendations for childhood lead screening.22 A safe blood level of lead is still uncertain. At one time, 25 μg/dL was considered safe. Surveys have shown abnormally low IQs in children with lead levels as low as 10 to 15 μg/dL.

Screening for lead toxicity involves use of capillary blood obtained from a finger stick to measure free erythrocyte protoporphyrin (EP). Elevated levels of EP result from the inhibition by lead of the enzymes required for heme synthesis in red blood cells. The EP test is useful in detecting high lead levels but usually does not detect levels below 20 to 25 μg/dL. Thus, capillary screening test values greater than 10 μg/dL should be confirmed with those from a venous blood sample. Because the symptoms of lead toxicity usually are vague, diagnosis is often delayed. Anemia may provide the first clues to the disorder. Laboratory tests are necessary to establish a diagnosis. Treatment involves removal of the lead source and, in cases of severe toxicity, administration of a chelating agent. Asymptomatic children with blood levels of 45 to 69 μg/dL usually are treated. A public health team should evaluate the source of lead because meticulous removal is needed.

**Mercury Toxicity.** Mercury has been used for industrial and medical purposes for hundreds of years. Mercury is toxic, and the hazards of mercury-associated occupational and accidental exposures are well known. Currently mercury and lead are the most toxic metals. Mercury is toxic in four primary forms: mercury vapor, inorganic divalent mercury, methyl mercury, and ethyl mercury.23 Depending on the form of mercury exposure, toxicity involving the central nervous system and kidney can occur.24

In the case of dental fillings, the concern involves mercury vapor being released into the mouth. However, the amount of mercury vapor released from fillings is very small. The main source of methyl mercury exposure is from consumption of long-lived fish, such as tuna and swordfish. Fish concentrate mercury from sediment in the water. Only certain types of fish pose potential risk, however, and types such as salmon have miniscule amounts or no mercury. Because the developing brain is more susceptible to mercury-induced damage, it is recommended that young children and pregnant and nursing women avoid consumption of fish known to contain high mercury content. Thimerosal is an ethyl mercury-containing preservative that helps prevent microorganism growth in vaccines. Due to the concern of this preservative, it is hardly ever used in the United States.

**Injury from Biologic Agents**

Biologic agents differ from other injurious agents in that they are able to replicate and can continue to produce their injurious effects. These agents range from submicroscopic viruses to the larger parasites. Biologic agents injure cells by diverse mechanisms. Viruses enter the cell and become incorporated into its DNA synthetic machinery. Certain bacteria elaborate exotoxins that interfere with cellular production of ATP. Other bacteria, such as the gram-negative bacilli, release endotoxins that cause cell injury and increased capillary permeability.

**Injury from Nutritional Imbalances**

Nutritional excesses and nutritional deficiencies predispose cells to injury. Obesity and diets high in saturated fats are thought to predispose persons to atherosclerosis. The body requires more than 60 organic and inorganic substances in amounts ranging from micrograms to grams. These nutrients include minerals, vitamins, certain fatty acids, and specific amino acids. Dietary deficiencies can occur in the form of starvation, in which there is a deficiency of all nutrients and vitamins, or because of a selective deficiency of a single nutrient or vitamin. Iron-deficiency anemia, scurvy, beriberi, and pellagra are examples of injury caused by the lack of specific vitamins or minerals. The protein and calorie deficiencies that occur with starvation cause widespread tissue damage.

**Mechanisms of Cell Injury**

The mechanisms by which injurious agents cause cell injury and death are complex. Some agents, such as heat, produce direct cell injury. Other factors, such as genetic derangements, produce their effects indirectly through metabolic disturbances and altered immune responses.18 There seem to be at least three major mechanisms whereby most injurious agents exert their effects:

- Free radical formation
- Hypoxia and ATP depletion
- Disruption of intracellular calcium homeostasis (Fig. 5.7)

**Free Radical Injury**

Many injurious agents exert damaging effects through reactive chemical species known as free radicals.25 Free radicals are highly reactive chemical species with an unpaired electron in the outer orbit (valence shell) of the molecule.18 In the literature, the unpaired electron is denoted by a dot, for example, •NO. The unpaired electron causes free radicals to be unstable and highly reactive, so that they react nonspecifically with molecules in the vicinity. Moreover, free radicals can establish chain reactions consisting of many events that generate new free radicals. In cells and tissues, free radicals react with proteins, lipids, and carbohydrates, thereby damaging cell membranes; inactivate enzymes; and damage nucleic acids that make up DNA. The actions of free radicals may disrupt and damage cells and tissues.

*Reactive oxygen species* (ROS) are oxygen-containing molecules that include free radicals such as superoxide (O₂•) and hydroxyl radical (OH•) and nonradicals such as hydrogen peroxide (H₂O₂).15 These molecules are produced endogenously by normal metabolic processes or cell activities, such as the metabolic burst that accompanies...
phagocytosis. However, exogenous causes, including ionizing and UV radiation, can cause ROS production in the body. Oxidative stress is a condition that occurs when the generation of ROS exceeds the ability of the body to neutralize and eliminate ROS. Oxidative stress can lead to oxidation of cell components, activation of signal transduction pathways, and changes in gene and protein expression. DNA modification and damage can occur as a result of oxidative stress. Although ROS and oxidative stress are clearly associated with cell and tissue damage, evidence shows that ROS do not always act in a random and damaging manner. Current studies have found that ROS are also important signaling molecules that are used in healthy cells to regulate and maintain normal activities and functions such as vascular tone and insulin and vascular endothelial growth factor signaling.

Oxidative damage has been implicated in many diseases. Mutations in the gene for SOD are linked with amyotrophic lateral sclerosis (ALS; so-called Lou Gehrig disease). Oxidative stress is thought to play an important role in the development of cancer. Reestablishment of blood flow after loss of perfusion, as occurs during heart attack and stroke, is associated with oxidative injury to vital organs. The endothelial dysfunction that contributes to the development, progression, and prognosis of cardiovascular disease is thought to be caused in part by oxidative stress.

In addition to the many diseases and altered health conditions associated with oxidative damage, oxidative stress has been linked with the age-related functional declines that underlie the process of aging.

Antioxidants are natural and synthetic molecules that inhibit the reactions of ROS with biologic structures or prevent the uncontrolled formation of ROS. Antioxidants include enzymatic and nonenzymatic compounds. Catalase can catalyze the reaction that forms water from hydrogen peroxide. Nonenzymatic antioxidants include carotenes (e.g., vitamin A), tocopherols (e.g., vitamin E), ascorbate (vitamin C), glutathione, flavonoids, selenium, and zinc.

**Hypoxic Cell Injury**

Hypoxia deprives the cell of oxygen and interrupts oxidative metabolism and the generation of ATP. The actual time necessary to produce irreversible cell damage depends on the degree of oxygen deprivation and the metabolic needs of the cell. Some cells, such as those in the heart, brain, and kidney, require large amounts of oxygen to provide energy to perform their functions. Brain cells, for example, begin to undergo permanent damage after 4 to 6 minutes of oxygen deprivation. A thin margin can exist between the time involved in reversible and irreversible cell damage. During hypoxic conditions,
hypoxia-inducible factors (HIFs) cause the expression of genes that stimulate red blood cell formation, produce ATP in the absence of oxygen, and increase angiogenesis29 (i.e., the formation of new blood vessels).

Hypoxia can result from an inadequate amount of oxygen in the air, respiratory disease, ischemia (i.e., decreased blood flow due to vasoconstriction or vascular obstruction), anemia, edema, or inability of the cells to use oxygen. Ischemia is characterized by impaired oxygen delivery and impaired removal of metabolic end products such as lactic acid. In contrast to pure hypoxia, which depends on the oxygen content of the blood and affects all cells in the body, ischemia commonly affects blood flow through limited numbers of blood vessels and produces local tissue injury. In some cases of edema, the distance for diffusion of oxygen may become a limiting factor in the delivery of oxygen. In hypermetabolic states, cells may require more oxygen than can be supplied by normal respiratory function and oxygen transport. Hypoxia also serves as the ultimate cause of cell death in other injuries. For example, a physical agent such as cold temperature can cause severe vasoconstriction and impair blood flow.

Hypoxia causes a power failure in the cell, with widespread effects on the cell’s structural and functional components. As oxygen tension in the cell falls, oxidative metabolism ceases and the cell reverts to anaerobic metabolism, using its limited glycogen stores in an attempt to maintain vital cell functions. Cellular pH falls as lactic acid accumulates in the cell. This reduction in pH can have adverse effects on intracellular structures and biochemical reactions. Low pH can alter cell membranes and cause chromatin clumping and cell shrinkage.

One important effect of reduced ATP is acute cell swelling caused by failure of the energy-dependent sodium/potassium (Na+/K+)-ATPase membrane pump, which extrudes sodium from and returns potassium to the cell. With impaired function of this pump, intracellular potassium levels decrease and sodium and water accumulate in the cell. The movement of water and ions into the cell is associated with multiple changes including widening of the endoplasmic reticulum, membrane permeability, and decreased mitochondrial function.15 In some instances, the cellular changes due to ischemia are reversible if oxygenation is restored. If the oxygen supply is not restored, however, there is a continued loss of enzymes, proteins, and ribonucleic acid through the hyperpermeable cell membrane. Injury to the lysosomal membranes results in the leakage of destructive lysosomal enzymes into the cytoplasm and enzymatic digestion of cell components. Leakage of intracellular enzymes through the permeable cell membrane into the extracellular fluid provides an important clinical indicator of cell injury and death.

**Impaired Calcium Homeostasis**

Calcium functions as an important second messenger and cytosolic signal for many cell responses. Various calcium-binding proteins, such as troponin and calmodulin, act as transducers for the cytosolic calcium signal. Calcium/calmodulin–dependent kinases indirectly mediate the effects of calcium on responses such as smooth muscle contraction and glyco-

Calcium levels are kept extremely low compared with extracellular levels. The low intracellular calcium levels are maintained by membrane-associated calcium/magnesium (Ca2+/Mg2+)–ATPase exchange systems. Ischemia and certain toxins lead to an increase in cytosolic calcium because of increased influx across the cell membrane and the release of calcium from intracellular stores. The increased calcium level may inappropriately activate a number of enzymes with potentially damaging effects. These enzymes include the phospholipases, responsible for damaging the cell membrane; proteases that damage the cytoskeleton and membrane proteins; ATPases that break down ATP and hasten its depletion; and endonucleases that fragment chromatin. Although it is known that injured cells accumulate calcium, it is unknown whether this is the ultimate cause of irreversible cell injury.

**Reversible Cell Injury and Cell Death**

The mechanisms of cell injury can produce sublethal and reversible cellular damage or lead to irreversible injury with...
cell destruction or death (Fig. 5.8). Cell destruction and removal can involve one of two mechanisms:

- Apoptosis, which is designed to remove injured or worn-out cells
- Cell death or necrosis, which occurs in irreversibly damaged cells

Reversible Cell Injury

Reversible cell injury, although impairing cell function, does not result in cell death. Two patterns of reversible cell injury can be observed under the microscope: cellular swelling and fatty change. Cellular swelling occurs with impairment of the energy-dependent Na⁺/K⁺-ATPase membrane pump, usually as the result of hypoxic cell injury.

Fatty changes are linked to intracellular accumulation of fat. When fatty changes occur, small vacuoles of fat disperse throughout the cytoplasm. The process is usually more ominous than cellular swelling, and although it is reversible, it usually indicates severe injury. These fatty changes may occur because normal cells are presented with an increased fat load or because injured cells are unable to metabolize the fat properly. In obese people, fatty infiltrates often occur within and between the cells of the liver and heart because of an increased fat load. Pathways for fat metabolism may be impaired during cell injury, and fat may accumulate in the cell as production exceeds use and export. The liver, where most fats are synthesized and metabolized, is particularly susceptible to fatty change, but fatty changes may also occur in the kidney, the heart, and other organs.

Programmed Cell Death

In most normal nontumor cells, the number of cells in tissues is regulated by balancing cell proliferation and cell death. Cell death occurs by necrosis or a form of programmed cell death called apoptosis. Apoptosis is a highly selective process that eliminates injured and aged cells, thereby controlling tissue regeneration. Cells undergoing apoptosis have characteristic morphologic features as well as biochemical changes. As shown in Figure 5.9, shrinking and condensation of the nucleus and cytoplasm occur. The chromatin aggregates at the nuclear envelope, and DNA fragmentation occurs. Then, the cell becomes fragmented into multiple apoptotic bodies in a manner that maintains the integrity of the plasma membrane and does not initiate inflammation. Changes in the plasma membrane induce phagocytosis of the apoptotic bodies by macrophages and other cells, thereby completing the degradation process.

Apoptosis is thought to be responsible for several normal physiologic processes, including the programmed destruction of cells during embryonic development, hormone-dependent involution of tissues, death of immune cells, cell death by cytotoxic T cells, and cell death in proliferating cell populations. During embryogenesis, in the development of a number of organs such as the heart, which begins as a pulsating tube and is gradually modified to become a four-chambered pump, apoptotic cell death allows for the next stage of organ development. It also separates the webbed fingers and toes of the developing embryo (Fig. 5.10). Apoptotic cell death occurs in the hormone-dependent involution of endometrial cells during the menstrual cycle and in the regression of breast tissue after weaning from breast-feeding. The control of immune cell numbers and destruction of autoreactive T cells in the thymus have been credited to apoptosis. Cytotoxic T cells and natural killer cells are thought to destroy target cells by inducing apoptotic cell death.
Apopoptosis is linked to many pathologic processes and diseases. For example, interference with apoptosis is known to be a mechanism that contributes to carcinogenesis.\(^\text{30}\) Apoptosis may also be implicated in neurodegenerative disorders such as Alzheimer disease, Parkinson disease, and ALS. However, the exact mechanisms involved in these diseases remain under investigation.

Two basic pathways for apoptosis have been described (Fig. 5.11). These are the extrinsic pathway, which is death receptor dependent, and the intrinsic pathway, which is death receptor independent. The execution phase of both pathways is carried out by proteolytic enzymes called caspases, which are present in the cell as procaspases and are activated by cleavage of an inhibitory portion of their polypeptide chain.

The extrinsic pathway involves the activation of receptors such as tumor necrosis factor (TNF) receptors and the Fas ligand receptor.\(^\text{31}\) Fas ligand may be expressed on the surface of certain cells such as cytotoxic T cells, or appear in a soluble form. When Fas ligand binds to its receptor, proteins congregate at the cytoplasmic end of the Fas receptor to form a death-initiating complex. The complex then converts procaspase-8 to caspase-8. Caspase-8, in turn, activates a cascade of caspases that execute the process of apoptosis.\(^\text{31}\) The end result includes activation of endonucleases that cause fragmentation of DNA and cell death. In addition to TNF and Fas ligand, primary signaling molecules known to activate the extrinsic pathway include TNF-related apoptosis-inducing ligand (TRAIL); the cytokine interleukin-1 (IL-1); and lipopolysaccharide (LPS), the endotoxin found in the outer cell membrane of gram-negative bacteria.

The intrinsic pathway, or mitochondrion-induced pathway, of apoptosis is activated by conditions such as DNA damage, ROS, hypoxia, decreased ATP levels, cellular senescence, and activation of the p53 protein by DNA damage.\(^\text{32}\) It involves the opening of mitochondrial membrane permeability pores with release of cytochrome c from the mitochondria into the cytoplasm. Cytoplasmic cytochrome c activates caspases, including caspase-3. Caspase-3 activation is a common step to both the extrinsic and intrinsic pathways. Furthermore, activation or increased levels of proapoptotic proteins, such as Bid and Bax, after caspase-8 activation in the extrinsic pathway can lead to mitochondrial release of cytochrome c, thereby bridging the two pathways for apoptosis. Many inhibitors of apoptosis within cells are known and thought to contribute to cancer and autoimmune diseases.\(^\text{33}\) The therapeutic actions of certain drugs may induce or facilitate apoptosis. Apoptosis continues to be an active area of investigation to better understand and treat a variety of diseases.

**Necrosis**

Necrosis refers to cell death in an organ or tissue that is still part of a living organism.\(^\text{15}\) Necrosis differs from apoptosis since it causes loss of cell membrane integrity and enzymatic breakdown of cell parts and triggers the inflammatory process.\(^\text{1}\) In contrast to apoptosis, which functions in removing cells so new cells can replace them, necrosis often interferes with cell replacement and tissue regeneration.

With necrotic cell death, there are marked changes in the appearance of the cytoplasmic contents and the nucleus. These changes often are not visible, even under the microscope, for hours after cell death. The dissolution of the necrotic cell or tissue can follow several paths. The cell can undergo liquefaction (i.e., liquefaction necrosis); it can be transformed to a gray, firm mass (i.e., coagulation necrosis); or it can be converted to a cheesy material by infiltration of fatlike substances (i.e., caseous necrosis).\(^\text{1}\) Liquefaction necrosis occurs when some of the cells die but their catalytic enzymes are not destroyed.\(^\text{1}\) An example of liquefaction necrosis is the softening of the center of an abscess with discharge of its contents. During coagulation necrosis, acidosis develops and denatures the enzymatic and structural proteins of the cell. This type of necrosis is
characteristic of hypoxic injury and is seen in infarcted areas.¹

**Infarction** (*i.e.*, tissue death) occurs when an artery supplying an organ or part of the body becomes occluded and no other source of blood supply exists. As a rule, the shape of the infarction is conical and corresponds to the distribution of the artery and its branches. An artery may be occluded by an embolus, a thrombus, disease of the arterial wall, or pressure from outside the vessel.

**Caseous necrosis** is a distinctive form of coagulation necrosis in which the dead cells persist indefinitely.¹ It is most commonly found in the center of tuberculosis granulomas, or tubercles.³

**Gangrene.** The term *gangrene* is applied when a considerable mass of tissue undergoes necrosis. Gangrene may be classified as dry or moist. In dry gangrene, the part becomes dry and shrinks, the skin wrinkles, and its color changes to dark brown or black. The spread of dry gangrene is slow, and its symptoms are not as marked as those of wet gangrene. The irritation caused by the dead tissue produces a line of inflammatory reaction (*i.e.*, line of demarcation) between the dead tissue of the gangrenous area and the healthy tissue. Dry gangrene usually results from interference with the arterial blood supply to a part without interference with venous return and is a form of coagulation necrosis.

In moist or wet gangrene, the area is cold, swollen, and pulseless. The skin is moist, black, and under tension. Blebs form on the surface, liquefaction occurs, and a foul odor is caused by bacterial action. There is no line of demarcation between the normal and diseased tissues, and the spread of tissue damage is rapid. Systemic symptoms are usually severe, and death may occur unless the condition can be arrested. Moist or wet gangrene primarily results from interference with venous return from the part. Bacterial invasion plays an important role in the development of wet gangrene and is responsible for many of its prominent symptoms. Dry gangrene is confined almost exclusively to the extremities, but moist gangrene may affect the internal organs or the extremities. If bacteria invade the necrotic tissue, dry gangrene may be converted to wet gangrene.

**Gas gangrene** is a special type of gangrene that results from infection of devitalized tissues by one of several *Clostridium* bacteria, most commonly *Clostridium perfringens.*¹ These anaerobic and spore-forming organisms are widespread in nature, particularly in soil. Gas gangrene is prone to occur in trauma and compound fractures in which dirt and debris are embedded. Some species have been isolated in the stomach, gallbladder, intestine, vagina, and skin of healthy people. Characteristic of this disorder are the bubbles of hydrogen sulfide gas that form in the muscle. Gas gangrene is a serious and potentially fatal disease. Antibiotics are used to treat the infection and surgical methods are used to remove the infected tissue. Amputation may be required to prevent spreading infection involving a limb. Hyperbaric oxygen therapy has been used, but clinical data supporting its efficacy have not been rigorously assessed.

### Cellular Aging

**Like adaptation and injury, aging is a process that involves the cells and tissues of the body. A number of theories have been proposed to explain the cause of aging. These theories are not mutually exclusive, and aging is most likely complex with multiple causes. The main theories of aging can be categorized based on evolutionary, molecular, cellular, and systems-level explanations.¹**

The *evolutionary theories* focus on genetic variation and reproductive success. After the reproductive years have passed, it is not clear that continued longevity contributes to the fitness of the species. Thus, "antiaging" genes would not necessarily be selected, preserved, and prevalent in the gene pool.

The *molecular theories* of cellular aging focus more on mutations or changes in gene expression. Because the appearance, properties, and function of cells depend on gene expression, this aspect is likely to be involved in aging at some level. Recent attention is being given to the so-called aging genes identified in model systems.

There are a number of *cellular theories of senescence* that are currently under investigation, including those that focus on telomere shortening, free radical injury, and apoptosis. It has been known since the mid-1960s that many cells in culture exhibit a limit in replicative capacity, the so-called Hayflick limit of about 50 population doublings. This limit seems to be related to the length of the telomeres, which are DNA sequences at the ends of chromosomes. Each time a cell divides, the telomeres shorten until a critical minimal length is attained, senescence ensues, and further cell replication does not occur. Some cells have telomerase, an enzyme that "rebuilds" telomeres and lessens or prevents shortening. Cancer cells have high levels of telomerase, which prevents senescence and contributes to the cellular immortality that characterizes cancer. Telomere shortening appears to be related to other theories of cellular causes of aging. For example, free radicals and oxidative damage can kill cells and hasten telomere shortening. Caloric restriction, which appears to increase longevity, may be related to reduced mitochondrial free radical generation owing to reduced methionine or other dietary amino acid intake.³⁴

Systems-level theories center on a decline in the integrative functions of organ systems such as the immunologic and neuroendocrine systems, which are necessary for overall control of other body systems. The immune system may decline with age and be less effective in protecting the body from infection or cancer. In addition, mutations and manipulations of genes such as *daf-2*, which is similar to human insulin/IGF-1 receptor genes, in the aging worm model *Caenorhabditis elegans* cause significant changes in longevity.³⁵ Pathways related to *daf-2* may be responsible for relationships between caloric restriction and prolonged life span in rodents and other animals. The mechanisms that regulate aging are likely to be complex and multifactorial, as will be any interventions to prolong aging.
IN SUMMARY

Cell injury can be caused by a number of agents, including physical agents, chemicals, biologic agents, and nutritional factors. Among the physical agents that generate cell injury are mechanical forces that produce tissue trauma, extremes of temperature, electricity, radiation, and nutritional disorders. Chemical agents can cause cell injury through several mechanisms: they can block enzymatic pathways, cause coagulation of tissues, or disrupt the osmotic or ionic balance of the cell. Biologic agents differ from other injurious agents in that they are able to replicate and continue to produce injury. Among the nutritional factors that contribute to cell injury are excesses and deficiencies of nutrients, vitamins, and minerals.

Injurious agents exert their effects largely through generation of free radicals, production of cell hypoxia, or dysregulation of intracellular calcium levels. Partially reduced oxygen species called free radicals are important mediators of cell injury in many pathologic conditions. They are an important cause of cell injury in hypoxia and after exposure to radiation and certain chemical agents. Lack of oxygen underlies the pathogenesis of cell injury in hypoxia and ischemia. Hypoxia can result from inadequate oxygen in the air, cardiorespiratory disease, anemia, or the inability of the cells to use oxygen. Increased intracellular calcium activates a number of enzymes with potentially damaging effects.

Injurious agents may produce sublethal and reversible cellular damage or may lead to irreversible cell injury and death. Cell death can involve two mechanisms: apoptosis or necrosis. Apoptosis involves controlled cell destruction and is the means by which the body removes and replaces cells that have been produced in excess, developed improperly, have genetic damage, or are worn out. Necrosis refers to cell death that is characterized by cell swelling, rupture of the cell membrane, and inflammation.

Like adaptation and injury, aging is a process that involves the cells and tissues of the body. A number of theories have been proposed to explain the complex causes of aging, including those based on evolutionary mechanisms that explain aging as a consequence of natural selection, in which traits that maximize the reproductive capacity of an individual are selected over those that maximize longevity; molecular theories, such as those that explain aging as a result of changes in gene expression; cellular theories that explain cellular senescence in relation to telomere length or molecular events, free radical damage, accumulated wear-and-tear, or apoptosis; and systems theories that attribute cellular aging to a decline in the integrative functions of organ systems such as the neuroendocrine and immunologic systems.

REVIEW EXERCISES

1. A 30-year-old man sustained a fracture of his leg 2 months ago. The leg has been encased in a cast, and he has just had it removed. He is amazed at the degree to which the muscles in his leg have shrunk.
   A. Would you consider this to be a normal adaptive response? Explain.
   B. Will these changes have an immediate and/or long-term effect on the function of the leg?
   C. What types of measures can be taken to restore full function to the leg?
2. A 45-year-old woman has been receiving radiation therapy for breast cancer.
   A. Explain the effects of ionizing radiation in eradicating the tumor cells.
   B. Why is the radiation treatment given in smaller divided, or fractionated, doses rather than as a single large dose?
   C. Partway through the treatment schedule, the woman notices that her skin over the irradiated area has become reddened and irritated. What is the reason for this?
3. People who have had a heart attack may experience additional damage once blood flow has been restored, a phenomenon referred to as reperfusion injury.
   A. What is the proposed mechanism underlying reperfusion injury?
   B. What factors might influence this mechanism?
4. Every day, blood cells in our body become senescent and die without producing signs of inflammation, yet massive injury or destruction of tissue, such as occurs with a heart attack, produces significant signs of inflammation.
   A. Explain.

Jennifer is a 1-day-old infant born after an uncomplicated vaginal delivery. She is noted to have poor muscle tone and irregular facies, including up-slanting almond-shaped eyes and a flat facial profile with a depressed nasal bridge. She also has a heart murmur, and the pediatrician is concerned about a potential heart condition. The pediatrician believes she may have Down syndrome (trisomy 21). A blood sample is sent for karyotype and found to be 47, XX, +21. Jennifer’s case is discussed further in this chapter and in Chapter 7.

Our genetic information is stored in the structure of deoxyribonucleic acid (DNA), an extremely stable macromolecule. Genetic information directs the function of our body cells, determines our appearance and how we respond to our environment, and serves as the unit of inheritance passed on from generation to generation. Genes also determine our disease susceptibility and how we react to drugs.

An understanding of the role that genetics plays in pathogenesis of disease has expanded greatly over the past century. It is now apparent that many diseases, including cancer, diabetes, and cardiovascular diseases, have a genetic component. In the case of cancer, recent genetic advances have led to new methods for early detection and more effective treatment. Advances in immunogenetics have made compatible blood transfusion and organ transplants a reality, and recombinant DNA technology has provided the methods for producing human insulin, growth hormone, and clotting factors. Perhaps the most extensive use of gene technology involved the Human Genome Project, begun in 1990 and completed in 2003, in which the entire human genetic complement (the genome) has been sequenced. This chapter includes discussions of genetic control of cell function, chromosomes, patterns of inheritance, and gene technology.
Proteins are responsible for the functional diversity of cells, they perform most biologic functions, and it is at their level that many regulatory processes take place, many disease processes occur, and most drug targets are found. The term proteome defines the complete set of proteins encoded by a genome. Proteomics, the study of the proteome, uses highly sophisticated technological methods to examine the molecular and biochemical events in a cell.
one nitrogen ring, and the purine bases, adenine (A) and guanine (G), which have two. The backbone of DNA consists of alternating groups of sugar and phosphoric acid, with the paired bases projecting inward from the sides of the sugar molecule.

**Double Helix and Base Pairing**

The native structure of DNA, as elucidated by James Watson and Frances Crick in 1953, is that of a spiral staircase, with the paired bases representing the steps (see Fig. 6.1). A precise complementary pairing of purine and pyrimidine bases occurs in the double-stranded DNA molecule in which A is paired with T and G is paired with C. Each nucleotide in a pair is on one strand of the DNA molecule, with the bases on opposite DNA strands bound together by hydrogen bonds that are extremely stable under normal conditions. The double-stranded structure of DNA molecules allows them to replicate precisely by separation of the two strands, followed by synthesis of two new complementary strands. Similarly, the base complementary pairing allows for efficient and correct repair of damaged DNA molecules.

Several hundred to almost 1 million base pairs can represent a gene, the size being proportional to the protein product it encodes. Of the two DNA strands, only one is used in transcribing the information for the cell’s protein-building machinery. The genetic information of one strand is meaningful and is used as a template for transcription; the complementary code of the other strand does not make sense and is ignored. Both strands, however, are involved in DNA duplication. Before cell division, the two strands of the helix separate and a complementary molecule is duplicated next to each original strand. Two strands become four strands. During cell division, the newly duplicated double-stranded molecules are separated and placed in each daughter cell by the mechanics of mitosis. As a result, each of the daughter cells again contains the meaningful strand and the complementary strand joined together as a double helix. In 1958, Meselson and Stahl characterized this replication of DNA as *semiconservative*, as opposed to conservative replication in which the parental strands reassociate when the two strands are brought together (Fig. 6.2).1

**Packaging of DNA**

The genome or total genetic content is distributed in chromosomes. Each human somatic cell (cells other than the gametes [sperm and ovum]) has 23 pairs of different chromosomes, one pair derived from the individual’s mother and the other from the father. One of the chromosome pairs consists of the sex chromosomes. Genes are arranged linearly along each chromosome. Each chromosome contains one continuous, linear DNA helix. The DNA in the longest chromosome is more than 7 cm in length. If the DNA of all 46 chromosomes were placed end to end, the total DNA would span a distance of about 2 m (>6 feet).

Because of their large size, DNA molecules are combined with several types of protein and small amounts of RNA into a coiled structure known as *chromatin*. The organization of DNA into chromatin is essential for controlling transcription and for packaging the molecule. Some DNA-associated proteins form binding sites for repressor molecules and hormones that regulate genetic transcription; others may block genetic transcription by preventing access of nucleotides to the surface of the DNA molecule.2 A specific group of proteins called *histones* is thought to control the folding of the DNA strands.2 Each double-stranded DNA molecule periodically coils around histones, which keeps the DNA organized.3 With cells that do not divide the DNA strands are in a less compact form called chromatin. Figure 6.3 illustrates how both the chromosomes and chromatin, which consist of chromosomal DNA, are coiled around histones.

Although solving the structural problem of how to fit a huge amount of DNA into the nucleus, the chromatin fiber, when complexed with histones and folded into various levels of compaction, makes the DNA inaccessible during the processes of replication and gene expression. To accommodate these processes, chromatin must be induced to change its structure, a process called *chromatin remodeling*.4 Several chemical interactions are now known to affect this process. One of these involves the acetylation of a histone amino acids group that is linked to the opening of the chromatin fiber and gene activation. Another important chemical modification involves the methylation of histone amino acids, which is correlated with gene inactivation.

**Genetic Code**

Four bases—guanine, adenine, cytosine, and thymine (uracil is substituted for thymine in RNA)—make up the alphabet of the genetic code. A sequence of three of these bases forms the
Rarely, accidental errors in duplication of DNA occur. These errors are called mutations. Mutations result from the substitution of one base pair for another, the loss or addition of one or more base pairs, or rearrangements of base pairs. Many of these mutations occur spontaneously, whereas others occur because of environmental agents, chemicals, and radiation. Mutations may arise in somatic cells or in germ cells. Only those DNA changes that occur in germ cells can be inherited.

Considering the millions of base pairs that must be duplicated in each cell division, it is not surprising that random changes in replication occur. Most of these defects are corrected by DNA repair mechanisms. Several repair mechanisms exist, and each depends on specific enzymes called endonucleases that recognize local distortions of the DNA helix, cleave the abnormal chain, and remove the distorted region. The gap is then filled when the correct deoxyribonucleotides, created by a DNA polymerase using the intact complementary strand as a template, are added to the cleaved DNA. The newly synthesized end of the segment is then joined to the remainder of the DNA strand by a DNA ligase. The normal regulation of these gene repair mechanisms is under the control of DNA repair genes. Loss of these gene functions renders the DNA susceptible to accumulation of mutations. When these affect protooncogenes or tumor suppressor genes, cancer may result.

Genetic Variability

As the Human Genome Project was progressing, it became evident that the human genome sequence is almost exactly (99.9%) the same in all people. It is the small variation (0.01%) in gene sequence (termed a haplotype) that is thought to account for the individual differences in physical traits, behaviors, and disease susceptibility. These variations are sometimes referred to as polymorphisms (from the existence of more than one morphologic or body form in a population). An international effort has been organized to develop a map (HapMap) of these variations with the intent of providing a link between genetic variations and common complex diseases such as cancer, heart disease, diabetes, and some forms of mental disease.

Mitochondrial DNA

In addition to nuclear DNA, part of the DNA of a cell resides in the mitochondria. Mitochondrial DNA is inherited from the mother by her offspring (i.e., matrilineal inheritance). It is a double-stranded closed circle, containing 37 genes, 24 of which are needed for mitochondrial DNA translation and 13 of which encode enzymes needed for oxidative metabolism. Replication of mitochondrial DNA depends on enzymes encoded by nuclear DNA. Thus, the protein-synthesizing apparatus and molecular components for oxidative metabolism are jointly derived from nuclear and mitochondrial genes. Genetic disorders of mitochondrial DNA, although rare, commonly affect tissues such as those of the neuromuscular system that have a high requirement for oxidative metabolism.

From Genes to Proteins

Although DNA determines the type of biochemical product needed by the cell and directs its synthesis, it is RNA through the process of translation, which is responsible for the actual assembly of the products.

RNA Structure and Function

RNA, like DNA, is a large molecule made up of a long string of nucleotides. However, it differs from DNA in three aspects of its structure. First, RNA is a single-stranded rather than a double-stranded molecule. Second, the sugar in each nucleotide of RNA is ribose instead of deoxyribose. Third, the pyrimidine base thymine in DNA is replaced by uracil in RNA.

Cells contain three types of RNA: messenger RNA (mRNA), ribosomal RNA (rRNA), and transfer RNA (tRNA). All three types of RNA are synthesized in the nucleus by RNA polymerase enzymes and then moved into the cytoplasm, where protein synthesis takes place. Messenger RNA carries the instructions for protein synthesis, obtained from the DNA molecule, into the cytoplasm. Transfer RNA reads the instructions and delivers the appropriate amino acids to the ribosome, where ribosomal RNA translates the instructions and provides the machinery needed for protein synthesis.

**Messenger RNA.** Messenger RNA is the template for protein synthesis. It is a long molecule containing several hundred to several thousand nucleotides. Each group of three nucleotides forms a codon that is exactly complementary to a nucleotide triplet of the DNA molecule. Messenger RNA is formed by a process called transcription. In this process, the weak hydrogen bonds of DNA are broken so that free RNA nucleotides can pair with their exposed DNA counterparts on the meaningful strand of the DNA molecule (see Fig. 6.4). As with the base pairing of the DNA strands, complementary RNA bases pair with the DNA bases. In RNA, uracil (U) replaces thymine and pairs with adenine. As with DNA, guanine pairs with cytosine.

**Ribosomal RNA.** The ribosome is the physical structure in the cytoplasm where protein synthesis takes place. Ribosomal RNA forms 60% of the ribosome, with the remainder of the ribosome composed of the structural proteins and enzymes needed for protein synthesis. As with the other types of RNA, rRNA is synthesized in the nucleus. Unlike the two other types of RNA, rRNA is produced in a specialized nuclear structure called the nucleolus. The formed rRNA combines with ribosomal proteins in the nucleus to produce the ribosome, which is then transported into the cytoplasm. On reaching the cytoplasm, most ribosomes become attached to the endoplasmic reticulum and begin the task of protein synthesis.

**Transfer RNA.** Transfer RNA is a clover-shaped molecule containing only 80 nucleotides, making it the smallest RNA molecule. Its function is to deliver the activated form of an amino acid to the protein that is being synthesized in the ribosomes. At least 20 different types of tRNA are known, each of which recognizes and binds to only one type of amino acid. Each tRNA molecule has two recognition sites: the first is complementary for the mRNA codon and the second for the amino acid.
Transcription

Transcription occurs in the cell nucleus and involves the synthesis of RNA from a DNA template (Fig. 6.4). Genes are transcribed by enzymes called RNA polymerases that generate a single-stranded RNA identical in sequence (with the exception of U in place of T) to one of the strands of DNA. It is initiated by the assembly of a transcription complex composed of RNA polymerase and other associated factors. This complex binds to the double-stranded DNA at a specific site called the promoter region. Within the promoter region, the so-called TATA box is located. The TATA box contains the crucial thymine–adenine–thymine–adenine (TATA) nucleotide sequence that RNA polymerase recognizes and binds to. This binding also requires transcription factors, a transcription initiation site, and other proteins. Transcription continues to copy the meaningful strand into a single strand of RNA as it travels along the length of the gene, stopping only when it reaches a termination site with a stop codon. On reaching the stop signal, the RNA polymerase enzyme leaves the gene and releases the RNA strand. The RNA strand then is processed.

Processing involves the addition of certain nucleic acids at the ends of the RNA strand and cutting and splicing of certain internal sequences. Splicing involves the removal of stretches of RNA. Because of the splicing process, the final mRNA sequence is different from the original DNA template. The retained protein-coding regions of the mRNA sequences are called exons and the regions between exons are called introns. The functions of the introns are unknown. They are thought to be involved in the activation or deactivation of genes during various stages of development.

Splicing permits a cell to produce a variety of mRNA molecules from a single gene. By varying the splicing segments of the initial mRNA, different mRNA molecules are formed. For example, in a muscle cell, the original tropomyosin mRNA is spliced in as many as 10 different ways, yielding distinctly different protein products. This permits different proteins to be expressed from a single gene and reduces how much DNA must be contained in the genome.

Translation

Translation occurs in the cytoplasm of the cell and involves the synthesis of a protein using its mRNA template. Proteins are made from a standard set of amino acids, which are joined end to end to form the long polypeptide chains of protein molecules. Each polypeptide chain may have as many as 100 to more than 300 amino acids in it. Besides tRNA, translation requires the coordinated actions of mRNA and rRNA (Fig. 6.5). Each of the 20 different tRNA molecules transports its specific amino acid to the ribosome for incorporation into the developing protein molecule. Messenger RNA provides the information needed for placing the amino acids in their proper order for each specific type of protein. During protein synthesis, mRNA contacts and passes through the ribosome, during which it “reads” the directions for protein synthesis. As mRNA passes through the ribosome, tRNA delivers the appropriate amino acids for attachment to the growing polypeptide chain. The long mRNA molecule usually travels through and directs protein synthesis in more than one ribosome at a time. After the first part of the mRNA is read by the first ribosome, it moves onto a second and a third. As a result, ribosomes that are actively involved in protein synthesis are often found in clusters called polyribosomes.
The process of translation is not over when the genetic code has been used to create the sequence of amino acids that constitute a protein. To be useful to a cell, this new polypeptide chain must fold up into its unique three-dimensional conformation. The folding of many proteins is made more efficient by special classes of proteins called molecular chaperones. Typically the function of a chaperone is to assist a newly synthesized polypeptide chain to attain a functional conformation as a new protein and then to assist the protein’s arrival at the site in the cell where the protein carries out its function. Molecular chaperones also assist in preventing the misfolding of existing proteins. Disruption of chaperoning mechanisms causes intracellular molecules to become denatured and insoluble. These denatured proteins tend to stick to one another, precipitate, and form inclusion bodies. The development of inclusion bodies is a common pathologic process in Parkinson, Alzheimer, and Huntington diseases.

A newly synthesized polypeptide chain may also need to combine with one or more polypeptide chains from the same or an adjacent chromosome, bind small cofactors for its activity, or undergo appropriate enzyme modification. During the posttranslation process, two or more peptide chains may combine to form a single product. For example, two α-globin chains and two β-globin chains combine to form the αβ-hemoglobin molecule. The protein products may also be modified chemically by the addition of various types of functional groups. For example, fatty acids may be added, providing hydrophobic regions for attachment to cell membranes. Other modifications may involve cleavage of the protein, either to remove a specific amino acid sequence or to split the molecule into smaller chains. As an example, the two chains that make up the circulating active insulin molecule, one containing 21 and the other 30 amino acids, were originally part of an 82-amino-acid proinsulin molecule.

**Regulation of Gene Expression**

Only about 2% of the genome encodes instructions for synthesis of proteins; the remainder consists of noncoding regions that serve to determine where, when, and in what quantity proteins are made. The degree to which a gene or particular group of genes is active is called gene expression. A phenomenon termed induction is an important process by which gene expression is increased. Gene repression is a process by which a regulatory gene acts to reduce or prevent gene expression. Activator and repressor sites commonly monitor levels of the synthesized product and regulate gene transcription through a negative feedback mechanism. Whenever product levels decrease, gene transcription is increased, and when levels increase, it is repressed.

Although control of gene expression can occur in multiple steps, many regulatory events occur at the transcription level. The initiation and regulation of transcription require the collaboration of a battery of proteins, collectively termed transcription factors. Transcription factors are a class of proteins that bind to their own specific DNA region and function to increase or decrease transcriptional activity of the genes. The role of transcription factors in gene expression explains why neurons and liver cells have completely different structures and functions although all the
Deoxyribonucleic acid (DNA) directs the synthesis of the many thousands of proteins that are contained in the different cells of the body. Although some of the proteins are structural proteins, the majority are enzymes that catalyze the different chemical reactions in the cell. Because DNA is located in the cell’s nucleus and protein synthesis takes place in the cytoplasm, a second type of nucleic acid—ribonucleic acid (RNA)—participates in the actual assembly of the proteins.

There are three types of RNA: messenger RNA (mRNA), ribosomal RNA (rRNA), and transfer RNA (tRNA) that participate in (1) the transcription of the DNA instructions for protein synthesis and (2) the translation of those instructions into the assembly of the polypeptides that make up the various proteins.

The genetic code is a triplet of four bases (adenine [A], thymine [T], guanine [G], and cytosine [C], with thymine in DNA being replaced with uracil [U] in RNA) that control the sequence of amino acids in a protein molecule that is being synthesized. The triplet RNA code is called a codon.

**Transcription**

Transcription involves copying the genetic code containing the instructions for protein synthesis from DNA to a complementary strand of mRNA. Transcription is initiated by an enzyme called RNA polymerase, which binds to a promoter site on DNA. Many other proteins, including transcription factors, function to increase or decrease transcriptional activity of the genes. After mRNA has been transcribed, it detaches from DNA and is processed by cutting, removing introns, and splicing the exon RNA sequences to produce a variety of mRNA molecules from a single gene. Once mRNA has been processed, it diffuses through the nuclear pores into the cytoplasm, where it controls protein synthesis.
Translation

The process of translation involves taking the instructions transcribed from DNA to mRNA and transferring them to the rRNA of ribosomes located in the cytoplasm. When the mRNA carrying the instructions for a particular protein comes in contact with a ribosome, it binds to a small subunit of the rRNA. It then travels through the ribosome where the transcribed instructions are communicated to the tRNA, which delivers and transfers the correct amino acid to its proper position on the growing peptide chain. There are 20 types of tRNA, one for each of the 20 different types of amino acid. Each type of tRNA carries an anticodon complementary to the mRNA codon calling for the amino acid carried by the tRNA, and it is the recognition of the mRNA codon by the tRNA anticodon that ensures the proper sequence of amino acids in a synthesized protein.

In order to be functional, the newly synthesized protein must be folded into its functional form, modified further, and then routed to its final position in the cell.

**Genetic Mediators of Embryonic Development**

Regulation of gene expression also plays an essential role in the developing embryo. During embryonic development, many thousands of genes are expressed to control axial specification (i.e., ventral/dorsal, anterior/posterior/medial/lateral, left/right), pattern formation (spatial arrangement of differentiated cells in body tissues and organs), and organogenesis (development of the different body organs). Many of these genes code transcription factors that produce signaling molecules. Two examples are *sonic hedgehog* and *fibroblast growth factor*. Signaling molecules bind to cells and are transported to the nucleus, where they initiate changes in gene expression. Depending on the embryonic tissue, these transcription factors and signaling molecules are produced temporally at various times during embryonic development.

Sonic hedgehog signaling is involved in many key developmental events at multiple times during embryogenesis. It participates in such diverse developmental steps as establishment of the left-to-right axis responsible for the rostral-caudal orientation of the nervous system, the separation of the brain into two cerebral hemispheres, right and left eye orientation, and the separation and development of the correct number of fingers and toes. Fibroblast growth factors participate in a wide variety of developmental processes, including cell migration, growth, and differentiation. They are widely expressed in developing bone, and many autosomal dominant disorders of bone growth are mutations of fibroblast growth factor receptor genes. The most prevalent of these is a condition called *achondroplasia*, which is characterized by short stature with limbs that are disproportionately shorter than the trunk and macrocephaly (large head).
In summary

Genes are the fundamental unit of information storage in the cell. They determine the types of proteins and enzymes made by the cell and therefore control inheritance and day-to-day cell function. Genetic information is stored in a stable macromolecule called DNA. Genes transmit information contained in the DNA molecule as a triplet code. The genetic code is determined by the arrangement of the nitrogenous bases of the four nucleotides (i.e., adenine, guanine, thymine [or uracil in RNA], and cytosine). Gene mutations represent accidental errors in duplication, rearrangement, or deletion of parts of the genetic code. Fortunately, most mutations are corrected by DNA repair mechanisms in the cell. The transfer of stored information from DNA into production of cell products is accomplished through a second type of nucleotide called RNA. Messenger RNA transcribes the instructions for product synthesis from the DNA molecule, undergoes splicing where the introns are removed, and moves to the cell’s cytoplasm, where ribosomal RNA uses the information to direct protein synthesis through the process known as translation. Transcription is initiated by RNA polymerase and other associated factors that bind to the double-stranded DNA at a specific site called the promoter region. Transfer RNA acts as a carrier system for delivering the appropriate amino acids to the ribosomes. The degree to which a gene or particular group of genes is active is called gene expression. Gene expression involves a set of complex interrelationships among different levels of control, including RNA transcription and post-translational processing. The initiation and regulation of RNA transcription are controlled by transcription factors that bind to specific DNA regions and function to regulate gene expression of the many different types of cells in the body. Posttranslational processing involves the proper folding of the newly synthesized polypeptide chain into its unique three-dimensional conformation. Special classes of proteins called molecular chaperones make the folding of many proteins more efficient. Posttranslational processing may also involve the combination of polypeptide chains from the same or an adjacent chromosome, the binding of small cofactors, or enzyme modification.

Most genetic information of a cell is organized, stored, and retrieved in small intracellular structures called chromosomes. Although the chromosomes are visible only in dividing cells, they retain their integrity between cell divisions. The chromosomes are arranged in pairs; one member of the pair is inherited from the father, the other from the mother. Each species has a characteristic number of chromosomes. In the human, 46 single or 23 pairs of chromosomes are present. Of the 23 pairs of human chromosomes, 22 are called autosomes and are alike in both males and females. Each of the 22 pairs of autosomes has the same appearance in all people, and each has been given a numeric designation for classification purposes (Fig. 6.6).

In the diploid cell, each of the 22 autosomal chromosomes has a homolog. Homologous chromosomes contain a similar series of genes; that is, they have similar sequences. They are not identical, however, because one homolog comes from the haploid sperm of the father and one from the haploid ovum of the mother. The sex chromosomes, which make up the 23rd pair of chromosomes, determine the sex of a person. All males have an X and Y chromosome (i.e., an X chromosome from the mother and a Y chromosome from the father); all females have two X chromosomes (i.e., one from each parent). The much smaller Y chromosome contains the male-specific region (MSY) that determines sex.13 This region comprises more than 95% of the length of the Y chromosome.

Only one X chromosome in the female is active in controlling the expression of genetic traits; however, both X chromosomes are activated during gametogenesis. In the female, the active X chromosome is invisible, but the inactive X chromosome can be visualized with appropriate nuclear staining. Inactivation is thought to involve the addition of a methyl group to the X chromosome. This inactive chromatin mass is seen as the Barr body in epithelial cells or as the drumstick chromosome in neutrophils.14 The genetic sex of a child can be determined by microscopic study of cell or tissue samples. The total number of X chromosomes is equal to the number of Barr bodies plus one (i.e., an inactive plus an active X chromosome). For example, the cells of a normal female have one Barr body and therefore a total of two X chromosomes. A normal male has no Barr bodies. Males with Klinefelter syndrome, who have one Y and two X chromosomes (one active and one inactive), exhibit one Barr body. In the female, whether the active X chromosome is derived from the mother or father is determined within a few days after conception, the selection being random for each postmitotic cell line. Thus, the tissues of normal women have on average 50% maternally derived and 50% paternally derived active X chromosomes. This is known as the Lyon principle.15

Cell Division

Two types of cell division occur in humans and many other animals: mitosis and meiosis. Mitosis involves duplication of somatic cells in the body and is represented by the cell cycle (Fig. 6.7). Meiosis is limited to replicating germ cells and takes place only once in a cell line. It results in the formation of gametes or reproductive cells (i.e., ovum and sperm), each
of which has only a single set of 23 chromosomes. Meiosis is typically divided into two distinct phases, meiosis I and meiosis II. Similar to mitosis, cells about to undergo the first meiotic division replicate their DNA during interphase. During metaphase I homologous autosomal chromosomes pair up, forming a synopsis or tetrad (two chromatids per chromosome). They are sometimes called bivalents. They do, however, pair up in several regions. The X and Y chromosomes are not homologs and do not form bivalents. While in metaphase I, an interchange of chromatid segments can occur. This process is called crossing-over (Fig. 6.8). Crossing-over allows for new combinations of genes, increasing genetic variability. After telophase I, each of the two daughter cells contains one member of each homologous pair of chromosomes and a sex chromosome (23 double-stranded chromosomes). No DNA synthesis occurs before meiotic division II. During anaphase II, the 23 double-stranded chromosomes (two chromatids) of each of the two daughter cells from meiosis I divide at their centromeres. Each subsequent daughter cell receives 23 single-stranded chromatids. Thus, a meiotic division of one cell forms a total of four daughter cells.

Meiosis, occurring only in the gamete-producing cells found in the testes or ovaries, has a different outcome in males and females. In males, meiosis (spermatogenesis) results in four viable daughter cells called spermatids that differentiate into sperm cells. In females, gamete formation or oogenesis is quite different. After the first meiotic division of a primary oocyte, a secondary oocyte and another structure called a polar body are formed. This small polar body contains little cytoplasm, but it may undergo a second meiotic division, resulting in two polar bodies. The secondary oocyte undergoes its second meiotic division, producing one mature oocyte and another polar body. Four viable sperm cells are produced during spermatogenesis, but only one ovum is produced by oogenesis.

**KEY POINTS**

**CHROMOSOMES**
- The DNA that stores genetic material is organized into 23 pairs of chromosomes. There are 22 pairs of autosomes, which are alike for males and females, and one pair of sex chromosomes, with XX pairing in females and XY pairing in males.
- Cell division involves the duplication of the chromosomes. Duplication of chromosomes in somatic cell lines involves mitosis, in which each daughter cell receives a pair of 23 chromosomes. Meiosis is limited to replicating germ cells and results in formation of a single set of 23 chromosomes.

**Chromosome Structure**
Cytogenetics is the study of the structure and numeric characteristics of the cell’s chromosomes. Chromosome studies can be done on any tissue or cell that grows and divides in culture. Lymphocytes from venous blood are frequently used for this purpose. After the cells have been cultured, a drug called colchicine is used to arrest mitosis in metaphase. A chromosome spread is prepared by fixing and spreading the chromosomes on a slide. Subsequently, appropriate staining techniques show the chromosomal banding patterns so they can be identified. The chromosomes are photographed, and the photomicrographs of each of the chromosomes are cut out and arranged in pairs according to a standard classification system (see Fig. 6.6). The completed picture is called a karyotype, and the procedure for preparing the picture is called karyotyping. A uniform system of chromosome

Crossing-over of DNA at the time of meiosis.

classification was originally formulated at the 1971 Paris Chromosome Conference and was later revised to describe the chromosomes as seen in more elongated prophase and prometaphase preparations.

In the metaphase spread, each chromosome takes the form of chromatids to form an “X” or “wishbone” pattern. Human chromosomes are divided into three types according to the position of the centromere. If the centromere is in the center and the arms are of approximately the same length, the chromosome is said to be metacentric; if it is not centered and the arms are of clearly different lengths, it is submetacentric; and if it is near one end, it is acrocentric. The short arm of the chromosome is designated as “p” for “petite,” and the long arm is designated as “q” for no other reason than it is the next

FIGURE 6.8  Crossing-over of DNA at the time of meiosis.
letter of the alphabet. The arms of the chromosome are indicated by the chromosome number followed by the p or q designation (e.g., 15p). Chromosomes 13, 14, 15, 21, and 22 have small masses of chromatin called satellites attached to their short arms by narrow stalks. At the ends of each chromosome are special DNA sequences called telomeres. Telomeres allow the end of the DNA molecule to be replicated completely.

The banding patterns of a chromosome are used in describing the position of a gene on a chromosome. Each arm of a chromosome is divided into regions, which are numbered from the centromere outward (e.g., 1, 2). The regions are further divided into bands, which are also numbered (Fig. 6.9). These numbers are used in designating the position of a gene on a chromosome. For example, Xp22 refers to band 2, region 2 of the short arm (p) of the X chromosome.

**FIGURE 6.9** The localization of inherited diseases as represented on the banded karyotype of the X chromosome. Notice the nomenclature of arms (p, q), regions (1, 2), and bands (e.g., 22 [region 2, band 2]). (From Rubin R., Strayer D. (Eds.). (2012). Rubin’s pathology: Clinicopathologic foundations of medicine (6th ed., p. 251). Philadelphia, PA: Lippincott Williams & Wilkins.)

The characteristics inherited from a person’s parents are inscribed in gene pairs found along the length of the chromosomes. Alternate forms of the same gene are possible (i.e., one inherited from the mother and the other from the father), and each may produce a different aspect of a trait.

**Definitions**

Genetics has its own set of definitions. The genotype of a person is the genetic information stored in the base sequence triplet code. The phenotype refers to the recognizable traits, physical or biochemical, associated with a specific genotype. Often, the genotype is not evident by available detection methods. More than one genotype may have the same phenotype. Some brown-eyed people are carriers of the code for blue eyes, and other brown-eyed people are not. Phenotypically, these two types of brown-eyed people are the same, but genotypically they are different.

With regard to a genetic disorder, not all people with a mutant gene are affected to the same extent. **Expressivity** refers to the manner in which the gene is expressed in the phenotype, which can range from mild to severe. **Penetrance** represents the ability of a gene to express its function. Seventy-five percent penetrance means 75% of people of a particular genotype present with a recognizable phenotype. Syndactyly and blue sclera are genetic mutations that often do not exhibit 100% penetrance.
The position of a gene on a chromosome is called its locus, and alternate forms of a gene at the same locus are called alleles. When only one pair of genes is involved in the transmission of information, the term single-gene trait is used. Single-gene traits follow the mendelian laws of inheritance.

Polygenic inheritance involves multiple genes at different loci, with each gene exerting a small additive effect in determining a trait. Multiple pairs of genes, many with alternate codes, determine most human traits, accounting for some dissimilar forms that occur with certain genetic disorders. Polygenic traits are predictable, but with less reliability than single-gene traits. Multifactorial inheritance is similar to polygenic inheritance in that multiple alleles at different loci affect the outcome; the difference is that multifactorial inheritance includes environmental effects on the genes.

Many other gene–gene interactions are known. These include epistasis, in which one gene masks the phenotypic effects of another nonallelic gene; multiple alleles, in which more than one allele affects the same trait (e.g., ABO blood types); complementary genes, in which each gene is mutually dependent on the other; and collaborative genes, in which two different genes influencing the same trait interact to produce a phenotype neither gene alone could produce.

Genetic Imprinting

Besides autosomal and sex-linked genes and mitochondrial inheritance, it was found that certain genes exhibit a “parent of origin” type of transmission in which the parental genomes do not always contribute equally in the development of a person (Fig. 6.10). The transmission of this phenomenon is called genetic imprinting. Although rare, it is estimated that approximately 100 genes exhibit genetic imprinting. Evidence suggests a genetic conflict occurs in the developing embryo: the male genome attempts to establish larger offspring, whereas the female prefers smaller offspring to conserve her energy for the current and subsequent pregnancies.

It was the pathologic analysis of ovarian teratomas (tumors made up of various cell types derived from an undifferentiated germ cell) and hydatidiform moles (gestational tumors made up of trophoblastic tissue) that yielded the first evidence of genetic imprinting. All ovarian teratomas were found to have a 46,XX karyotype. The results of detailed chromosomal polymorphism analysis confirmed that these tumors developed without the paternally derived genome. Conversely, analysis of hydatidiform moles suggested that they were tumors of paternal origin.

Well-known examples of genomic imprinting are the transmission of the mutations in Prader-Willi and Angelman syndromes. Both syndromes exhibit mental retardation as a common feature. It was also found that both disorders had the same deletion in chromosome 15. When the deletion is inherited from the mother, the infant presents with Angelman (“happy puppet”) syndrome. When the same deletion is inherited from the father, Prader-Willi syndrome results.

A related chromosomal disorder is uniparental disomy. This occurs when two chromosomes of the same number are inherited from one parent. Normally, this is not a problem except in cases where a chromosome has been imprinted by a parent. If imprinting inactivates an allele, the offspring will have only one working copy of the chromosome, resulting in possible problems.
**TRANSMISSION OF GENETIC INFORMATION**

- The transmission of information from one generation to the next is vested in genetic material transferred from each parent at the time of conception.
- Mendelian, or single-gene, patterns of inheritance include autosomal dominant and recessive traits that are transmitted from parents to their offspring in a predictable manner. Polygenic inheritance, which involves multiple genes, and multifactorial inheritance, which involves multiple genes as well as environmental factors, are less predictable.

**Mendel’s Laws**

A main feature of inheritance is predictability: given certain conditions, the likelihood of the occurrence or recurrence of a specific trait is remarkably predictable. The units of inheritance are the genes, and the pattern of single-gene expression can often be predicted using Mendel’s laws of genetic transmission. Techniques and discoveries since Gregor Mendel’s original work was published in 1865 have led to some modification of the original laws.

Mendel discovered the basic pattern of inheritance by conducting carefully planned experiments with simple garden peas. Experimenting with several phenotypic traits in peas, Mendel proposed that inherited traits are transmitted from parents to offspring by means of independently inherited factors—now known as genes—and that these factors are transmitted as recessive and dominant traits. Mendel labeled dominant factors (his round peas) “A” and recessive factors (his wrinkled peas) “a.” Geneticists continue to use capital letters to designate dominant traits and lowercase letters to designate recessive traits. The possible combinations that can occur with transmission of single-gene dominant and recessive traits can be described by constructing a figure called a **Punnett square** using capital and lowercase letters (Fig. 6.11).

The observable traits of single-gene inheritance are inherited by the offspring from the parents. During maturation, the primordial germ cells (i.e., sperm and ovum) of both parents undergo meiosis, or reduction division, in which the number of chromosomes is divided in half (from 46 to 23). At this time, the two alleles from a gene locus separate so that each germ cell receives only one allele from each pair (i.e., Mendel’s first law). According to Mendel’s second law, the alleles from the different gene loci segregate independently and recombine randomly in the zygote. People in whom the two alleles of a given pair are the same (AA or aa) are called **homozygotes. Heterozygotes** have different alleles (Aa) at a gene locus. A **recessive trait is one expressed only in a homozygous pairing; a dominant trait is one expressed in either a homozygous or a heterozygous pairing. All people with a dominant allele (depending on the penetrance of the genes) manifest that trait. A **carrier** is a person who is heterozygous for a recessive trait and does not manifest the trait. For example, the genes for blond hair are recessive and those for brown hair are dominant. Therefore, only people with a genotype having two alleles for blond hair would be blond; people with either one or two brown alleles would have brown hair.

**Pedigree**

A pedigree is a graphic method (see Figs. 6.10 and 6.11) for portraying a family history of an inherited trait. It is constructed from a carefully obtained family history and is useful for tracing the pattern of inheritance for a particular trait.

**IN SUMMARY**

Inheritance represents the likelihood of the occurrence or recurrence of a specific genetic trait. The **genotype** refers to information stored in the genetic code of a person, whereas the **phenotype** represents the recognizable traits, physical and biochemical, associated with the genotype. **Expressivity** refers to the expression of a gene in the phenotype, and penetrance is the ability of a gene to express its function. The point on the DNA molecule that controls the inheritance of a particular trait is called a **gene locus.** Alternate forms of a gene at a gene locus are called **alleles.** The alleles at a gene locus may carry recessive or dominant traits. A recessive trait is one expressed only when two copies (homozygous) of the recessive allele are present. Dominant traits are expressed with either homozygous or heterozygous pairing of the alleles. A pedigree is a graphic method for portraying a family history of an inherited trait.
The past several decades have seen phenomenal advances in the field of genetics. These advances have included the assembly of physical and genetic maps through the Human Genome Project, the establishment of the International HapMap Project to map the haplotypes of the many closely related single nucleotide polymorphisms in the human genome, and the development of methods for applying the technology of these projects to the diagnosis and treatment of disease. Many health care professions also have established clinical competencies for their specific professions regarding genomics and genetics since the application of genetics is becoming more evident in all areas of disease screening and management. There are multiple new genetic diagnostics being used that are able to assess patients for various genetic alterations. Information obtained from these technologies greatly assists in planning the care and specifically pharmacological management of many types of diseases. Health care professionals need to be able to answer questions and explain to patients and families genetic information and how this knowledge may or may not influence the course of one’s health.

Genetic Mapping

Genetic mapping is the assignment of genes to specific chromosomes or parts of the chromosome. Another type of mapping strategy, the haplotype map, focuses on identifying the slight variations in the human genome that affect an individual’s susceptibility to disease and responses to environmental factors such as microbes, toxins, and drugs.

There are two types of gene maps: genetic maps and physical maps. Genetic maps are like highway maps. They use linkage studies (e.g., dosage, hybridization) to estimate the distances between chromosomal landmarks (i.e., gene markers). Physical maps are similar to a surveyor’s map. They make use of cytogenetic and molecular techniques to determine the actual, physical locations of genes on chromosomes. Genetic maps and physical maps have been refined over the decades. The earliest mapping efforts localized genes on the X chromosome. The initial assignment of a gene to a particular chromosome was made in 1911 for the color blindness gene inherited from the mother (i.e., following the X-linked pattern of inheritance). In 1968, the specific location of the Duffy blood group on the long arm of chromosome 1 was determined.

The Human Genome Project

The Human Genome Project, initiated in 1990 and completed in 2003, sought to identify all the genes in the human genome. The international project was charged with developing genetic and physical maps that allowed the precise location of genes and with exploring technologies that would enable the sequencing of large amounts of DNA with high accuracy and low cost. Some of what was discovered was quite unexpected, including the revelation that humans have a mere 30,000 genes, rather than the predicted 100,000. Another surprising finding was that, on an average, any two people share 99.9% of their DNA sequence, indicating that the remarkable diversity among people is vested in about 0.1% of our DNA.1,2 To date, the locations of more than 25,000 genes have been mapped to a specific chromosome, and most of them to a specific region on the chromosome.3 However, genetic mapping is continuing so rapidly that these numbers are constantly being updated. An excellent source of articles regarding specific chromosome sequencing in humans is the National Center for Biotechnology Information (NCBI) (www.ncbi.nlm.nih.gov/index.html).4 Another source is the Genome Data Base, a central database for mapped genes and an international repository for most mapping information.5

Genetic Mapping Methods

Many methods have been used for developing genetic maps. The most important ones are family linkage studies, gene dosage methods, and hybridization studies. Often, the specific assignment of a gene is made using information from several mapping techniques.

Linkage Studies. Linkage studies assume that genes occur in a linear array along the chromosomes. During meiosis, the paired chromosomes of the diploid germ cell exchange genetic material because of the crossing-over phenomenon (see Fig. 6.8). This exchange usually involves more than one gene; large blocks of genes (representing large portions of the chromosome) are usually exchanged. Although the point at which one block separates from another occurs randomly, the closer together two genes are on the same chromosome, the greater the chance is that they will be passed on together to the offspring. When two inherited traits occur together at a rate greater than would occur by chance alone, they are said to be linked.

Several methods take advantage of the crossing-over and recombination of genes to map a particular gene. In one method, any gene that is already assigned to a chromosome can be used as a marker to assign other linked genes. For example, it was found that an extra long chromosome 1 and the Duffy blood group were inherited as a dominant trait, placing the position of the blood group gene close to the extra material on chromosome 1. Color blindness has been linked to classic hemophilia A (i.e., lack of factor VIII) in some pedigrees; hemophilia A has been linked to glucose-6-phosphate dehydrogenase deficiency in others; and color blindness has...
been linked to glucose-6-phosphate dehydrogenase deficiency in still others. Because the gene for color blindness is found on the X chromosome, all three genes must be found in a small section of the X chromosome. Linkage analysis can be used clinically to identify affected persons in a family with a known genetic defect. Males, because they have one X and one Y chromosome, are said to be hemizygous for sex-linked traits. Females can be homozygous or heterozygous for sex-linked traits. Heterozygous females are known as carriers for X-linked defects.

One autosomal recessive disorder that has been successfully diagnosed prenatally by linkage studies using amniocentesis is congenital adrenal hyperplasia (due to 21-hydroxylase deficiency), which is linked to an immune response gene (human leukocyte antigen [HLA]) type. Postnatal linkage studies have been used in diagnosing hemochromatosis, which is closely linked to another HLA type. People with this disorder are unable to metabolize iron, and it accumulates in the liver and other organs. It cannot be diagnosed by conventional means until irreversible damage has been done. Given a family history of the disorder, HLA typing can determine if the gene is present, and if it is present, dietary restriction of iron intake may be used to prevent organ damage.

**Gene Dosage Studies.** Dosage studies involve measuring enzyme activity. Autosomal genes are normally arranged in pairs, and normally both are expressed. If both alleles are present and both are expressed, the activity of the enzyme should be 100%. If one member of the gene pair is missing, only 50% of the enzyme activity is present, reflecting the activity of the remaining normal allele.

**Hybridization Studies.** A recent biologic discovery revealed that two somatic cells from different species, when grown together in the same culture, occasionally fuse to form a new hybrid cell. Two types of hybridization methods are used in genomic studies: somatic cell hybridization and in situ hybridization.

Somatic cell hybridization involves the fusion of human somatic cells with those of a different species (typically, the mouse) to yield a cell containing the chromosomes of both species. Because these hybrid cells are unstable, they begin to lose chromosomes of both species during subsequent cell divisions. This makes it possible to obtain cells with different partial combinations of human chromosomes. The enzymes of these cells are then studied with the understanding that for an enzyme to be produced, a certain chromosome must be present and, therefore, the coding for the enzyme must be located on that chromosome.

In situ hybridization involves the use of specific sequences of DNA or RNA to locate genes that do not express themselves in cell culture. DNA and RNA can be chemically tagged with radioactive or fluorescent markers. These chemically tagged DNA or RNA sequences are used as probes to detect gene location. The probe is added to a chromosome

spread after the DNA strands have been separated. If the probe matches the complementary DNA of a chromosome segment, it hybridizes and remains at the precise location (therefore the term in situ) on a chromosome. Radioactive or fluorescent markers are used to find the location of the probe.

**Haptype Mapping**

As work on the Human Genome Project progressed, many researchers reasoned that identifying the common patterns of DNA sequence variations in the human genome would be possible. An international project, known as the International HapMap Project, was organized with the intent of developing a haplotype map of these variations. One of the findings of the Human Genome Project was that the genome sequence was 99.9% identical for all people. It is anticipated that the 0.1% variation may greatly affect a person’s response to drugs, toxins, and predisposition to various diseases. Sites in the DNA sequence where people differ at a single DNA base are called single nucleotide polymorphisms (SNPs, pronounced “snips”). A haplotype consists of the many closely linked SNPs on a single chromosome that generally are passed as a block from one generation to another in a particular population. One of the motivating factors behind the HapMap Project was the realization that the identification of a few SNPs was enough to uniquely identify the haplotypes in a block. The specific SNPs that identify the haplotypes are called tag SNPs. A HapMap is a map of these haplotype blocks and their tag SNPs. This approach reduces the number of SNPs required to examine an entire genome and make genome scanning methods much more efficient in finding regions with genes that contribute to disease development. Much attention has focused on the use of SNPs to decide whether a genetic variant is associated with a higher risk of disease susceptibility in one population versus another. Pharmacogenetics addresses the variability of drug response due to inherited characteristics in people, allowing identification of people who can be expected to respond favorably to a drug and those who can be expected to experience adverse reactions. This results in safer, more effective, and more cost-efficient use of medications.

**Recombinant DNA Technology**

The term recombinant DNA refers to a combination of DNA molecules that are not found together in nature. Recombinant DNA technology makes it possible to identify the DNA sequence in a gene and produce the protein product encoded by a gene. The specific nucleotide sequence of a DNA fragment can often be identified by analyzing the amino acid sequence and mRNA codon of its protein product. Short sequences of base pairs can be synthesized, radioactively labeled, and subsequently used to identify their complementary sequence. In this way, identifying normal and abnormal gene structures is possible.

Tests of DNA sequences are particularly useful in identifying polymorphisms, including the previously discussed SNPs, that are associated with various diseases. Because
genetic variations are so distinctive, DNA fingerprinting (analysis of DNA sequence differences) can be used to determine family relationships or help identify persons involved in criminal acts. The methods of recombinant DNA technology can also be used in the treatment of disease. For example, recombinant DNA technology is used in the manufacture of human insulin that is used to treat diabetes mellitus.

**Gene Isolation and Cloning**

The gene isolation and cloning methods used in recombinant DNA technology rely on the fact that the genes of all organisms, from bacteria through mammals, are based on a similar molecular organization. Gene cloning requires cutting a DNA molecule apart, modifying and reassembling its fragments, and producing copies of the modified DNA, its mRNA, and its gene product. The DNA molecule is cut apart by using a bacterial enzyme, called a restriction enzyme, that binds to DNA wherever a particular short sequence of base pairs is found and cleaves the molecule at a specific nucleotide site. In this way, a long DNA molecule can be broken down into smaller, discrete fragments, one of which presumably contains the gene of interest. Many restriction enzymes are commercially available that cut DNA at different recognition sites.

The restrictive fragments of DNA can often be replicated through insertion into a unicellular organism, such as a bacterium. To do this, a cloning vector such as a bacterial virus or a small DNA circle that is found in most bacteria, called a plasmid, is used. Viral and plasmid vectors replicate autonomously in the host bacterial cell. During gene cloning, a bacterial vector and the DNA fragment are mixed and joined by a special enzyme called a DNA ligase. The recombinant vectors formed are then introduced into a suitable culture of bacteria, and the bacteria are allowed to replicate and express the recombinant vector gene. Sometimes, mRNA taken from a tissue that expresses a high level of the gene is used to produce a complementary DNA molecule that can be used in the cloning process. Because the fragments of the entire DNA molecule are used in the cloning process, additional steps are taken to identify and separate the clone that contains the gene of interest.

**Pharmaceutical Applications**

Recombinant DNA technology has also made it possible to produce proteins that have therapeutic properties. One of the first products to be produced was human insulin. Recombinant DNA corresponding to the A chain of human insulin was isolated and inserted into plasmids that were in turn used to transform *Escherichia coli*. The bacteria then synthesized the insulin chain. A similar method was used to obtain the B chains. The A and B chains were then mixed and allowed to fold and form disulfide bonds, producing active insulin molecules. Human growth hormone has also been produced in *E. coli*. More complex proteins are produced in mammalian cell culture using recombinant DNA techniques. These include erythropoietin, which is used to stimulate red blood cell production; factor VIII, which is used to treat hemophilia; and tissue plasminogen activator (tPA), which is frequently administered after a heart attack to dissolve thrombi.

**DNA Fingerprinting**

The technique of DNA fingerprinting is based in part on those techniques originally used in recombinant DNA technology and on those used in medical genetics to detect slight variations in the genomes of different individuals. Using restriction enzymes, DNA is cleaved at specific regions (Fig. 6.12). The DNA fragments are separated according to size by electrophoresis and denatured (by heating or treating chemically) so that all the DNA is single stranded. The single-stranded DNA is then transferred to nitrocellulose paper, baked to attach the DNA to the paper, and treated with series of radioactive probes. After the radioactive probes have been allowed to bond with the denatured DNA, radiography is used to reveal the labeled DNA fragments.

When used in forensic pathology, this procedure is applied to specimens from the suspect and the forensic specimen. Banding patterns are then analyzed to see if they match. With conventional methods of analysis of blood and serum enzymes, a 1 in 100 to 1000 chance exists that the two specimens match because of chance. With DNA fingerprinting, these odds are 1 in 100,000 to 1 million.

When necessary, the polymerase chain reaction (PCR) can be used to amplify specific segments of DNA. It is particularly suited for amplifying regions of DNA for clinical and forensic testing procedures because only a small sample of DNA is required as the starting material. Regions of DNA can be amplified from a single hair or drop of blood or saliva.

**Gene Therapy**

Although quite different from inserting genetic material into a unicellular organism such as bacteria, techniques are available for inserting genes into the genome of intact multicellular plants and animals. Promising delivery vehicles for these genes are the adenoviruses. These viruses are ideal vehicles because their DNA does not become integrated into the host genome. However, repeated inoculations are often needed because the body’s immune system usually targets cells expressing adenovirus proteins. Sterically stable liposomes also show promise as DNA delivery mechanisms. This type of therapy is one of the more promising methods for the treatment of genetic disorders such as cystic fibrosis, certain cancers, and many infectious diseases.

Two main approaches are used in gene therapy: transferred genes can replace defective genes or they can selectively inhibit deleterious genes. Cloned DNA sequences are usually the compounds used in gene therapy. However, the introduction of the cloned gene into the multicellular organism can influence only the few cells that get the gene. An answer to this problem would be the insertion of the gene into a sperm or ovum; after fertilization, the gene would be replicated in all of the differentiating cell types. Even so, techniques for cell insertion are limited. Not only are moral and ethical issues involved, but these techniques cannot direct the inserted DNA...
to attach to a particular chromosome or supplant an existing gene by knocking it out of its place.

To date, gene therapy has been used successfully to treat children with severe combined immunodeficiency disease, and in a suicide gene transfer to facilitate treatment of graft-versus-host disease after donor lymphocyte infusion.

### RNA Interference Technology

One approach of gene therapy focuses on the previously described replacement of missing or defective genes. However, several genetic disorders are due not to missing genes but to faulty gene activity. With this in mind, some scientists are approaching the problem by using RNA interference (RNAi) to stop genes from making unwanted disease proteins. RNAi is a naturally occurring process in which small pieces of double-stranded RNA (small interfering RNA [siRNA]) suppress gene expression. Scientists believe that RNAi may have originated as a defense against viral infections and potentially harmful genomic invaders. In viral infections, RNAi would serve to control the infection by preventing the synthesis of viral proteins.

With the continued refinement of techniques to silence genes, RNAi has already had a major impact on molecular biology. For example, it has given scientists the ability to practice reverse genomics, in which a gene’s function can be inferred through silencing its expression. Increasingly, pharmaceutical companies are using RNAi to identify disease-related drug targets. There also is considerable interest in harnessing RNAi for therapeutic purposes, including the treatment of human immunodeficiency virus (HIV) infection and hepatitis C. Before this can occur, however, the therapeutic methods must be shown to be safe and effective, and obstacles to delivering the RNAi into targeted cells must be overcome. It is difficult for RNA to cross the cell membrane, and enzymes in the blood quickly break it down.

### IN SUMMARY

The genome is the gene complement of an organism. Genomic mapping is a method used to assign genes to particular chromosomes or parts of a chromosome. The most important ones used are family linkage studies, gene dosage methods, and hybridization studies. Often the specific assignment of a gene is determined by using information from several mapping techniques. Linkage studies assign a chromosome location to genes based on their close association with other genes of known location. Recombinant DNA studies involve the extraction of specific types of mRNA used in synthesis of complementary DNA strands. The complementary DNA strands, labeled with a radioisotope, bind with the genes for which they are complementary and are used as gene probes. A haplotype consists of the many closely linked SNPs on a single chromosome that generally are passed as a block from one generation...
to another in a particular population. The International HapMap Project has been developed to map the SNPs on the human genome with the anticipation that it may be useful in the prediction and management of disease.

Genetic engineering has provided the methods for manipulating nucleic acids and recombining genes (recombinant DNA) into hybrid molecules that can be inserted into unicellular organisms and reproduced many times over. As a result, proteins that formerly were available only in small amounts can now be made in large quantities once their respective genes have been isolated. DNA fingerprinting, which relies on recombinant DNA technologies and those of genetic mapping, is often used in forensic investigations. A newer strategy for management of genetic disorders focuses on gene silencing by using RNAi to stop genes from making unwanted disease proteins.

**REVIEW EXERCISES**

1. The Human Genome Project has revealed that humans have only 30,000 to 35,000 genes. Only about 2% of the genome encodes instructions for protein synthesis, whereas 50% consists of repeat sequences that do not code proteins.
   A. Use this information to explain how this small number of protein-encoding genes is able to produce the vast array of proteins needed for organ and structural development in the embryo, as well as those needed for normal function of the body in postnatal life.

2. A child about to undergo surgery is typed for possible blood transfusions. His parents are told that he is type O positive. Both his mother and father are type A positive. A. How would you explain this variation in blood type to the parents?

3. More than 100,000 people die of adverse drug reactions each year; another 2.2 million experience serious reactions, whereas others fail to respond at all to the therapeutic actions of drugs.
   A. Explain how the use of information about single nucleotide polymorphisms (SNPs) might be used to map individual variations in drug responses.

4. Human insulin, prepared by recombinant DNA technology, is used for the treatment of diabetes mellitus.
   A. Explain the techniques used for the production of a human hormone with this technology.

Congenital defects, sometimes called birth defects, are abnormalities of a body structure, function, or metabolism that are present at birth. They affect more than 185,000 infants discharged from the hospital in the United States each year and are the leading cause of infant death. Birth defects may be caused by genetic factors (i.e., single-gene or multifactorial inheritance or chromosomal aberrations) or environmental factors that are active during embryonic or fetal development (e.g., maternal disease, infections, or drugs taken during pregnancy). Although congenital defects are present at birth, genetic disorders may make their appearance later in life. This chapter provides an overview of genetic and congenital disorders and is divided into three parts:

1. Genetic and chromosomal disorders
2. Disorders due to environmental agents
3. Diagnosis and counseling

A genetic disorder can be described as a discrete event that affects gene expression in a group of cells related to each other by gene linkage. Most genetic disorders are caused by changes in the deoxyribonucleic acid (DNA) sequence that alters the synthesis of a single gene product. Others are a result of chromosomal aberrations that trigger deletion or duplication errors. Some genetic disorders are a result of an abnormal number of chromosomes.
The genes on each chromosome are arranged in pairs and in strict order, with each gene occupying a specific location or locus. The two members of a gene pair, one inherited from the mother and the other from the father, are called alleles. If the members of a gene pair are identical (i.e., code the exact same gene product), the person is homozygous, and if the two members are different, the person is heterozygous. The genetic composition of a person is called a genotype, whereas the phenotype is the observable expression of a genotype in terms of morphologic, biochemical, or molecular traits. If the trait is expressed in the heterozygote (one member of the gene pair codes for the trait), it is said to be dominant. If it is expressed only in the homozygote (both members of the gene pair code for the trait), it is recessive.

Although gene expression usually follows a dominant or recessive pattern, it is possible for both alleles of a gene pair to be fully expressed in the heterozygote, a condition called codominance. Many genes have only one normal version, which geneticists call the wild-type allele. Other genes have more than one normal allele (alternate forms) at the same locus. This is called polymorphism. Blood group inheritance (e.g., AO, BO, AB) is an example of codominance and polymorphism.

A gene mutation is a biochemical event such as nucleotide change, deletion, or insertion that produces a new allele. A single mutant gene may be expressed in many different parts of the body. Marfan syndrome, for example, is a defect in a connective tissue protein that has widespread effects involving skeletal, eye, and cardiovascular structures. In other single-gene disorders, the same defect can be caused by mutations at several different loci. Childhood deafness can result from many different types of autosomal recessive mutations.

Genetic disorders can involve a single-gene trait, a multifactorial inheritance, a chromosomal abnormality, or a mitochondrial gene disorder. The disorder may be inherited as a family trait or arise as a sporadic case due to a new mutation.

Single-Gene Disorders

Single-gene disorders are caused by a defective or mutant allele at a single gene locus and follow mendelian patterns of inheritance. Single-gene disorders are primarily disorders of the pediatric age group. Less than 10% manifest after puberty and only 1% after the reproductive years.

Single-gene disorders are characterized by their patterns of transmission, which usually are obtained through a family genetic history. The patterns of inheritance depend on whether the phenotype is dominant or recessive and whether the gene is located on an autosomal or sex chromosome. In addition to disorders caused by mutations of genes located on the chromosomes located within the nucleus, another class of disorders with a maternal pattern of inheritance involves the mitochondrial genome.

Virtually all single-gene disorders lead to formation of an abnormal protein or decreased production of a gene product. The disorder can result in a defective enzyme or decreased amounts of an enzyme, defects in receptor proteins and their function, alterations in nonenzyme proteins, or mutations resulting in unusual reactions to drugs. Table 7.1 lists some of the common single-gene disorders and their manifestations.

Autoosomal Dominant Disorders

In autosomal dominant disorders, a single mutant allele from an affected parent is transmitted to an offspring regardless of sex. The affected parent has a 50% chance of transmitting the disorder to each offspring (Fig. 7.1). The unaffected relatives of the parent or unaffected siblings of the offspring do not transmit the disorder. In many conditions, the age of onset is delayed, and the signs and symptoms of the disorder do not appear until later in life, as in Huntington chorea.

Autosomal dominant disorders also may manifest as a new mutation. Whether the mutation is passed on to the next generation depends on the affected person’s reproductive capacity. Many autosomal dominant mutations are accompanied by reduced reproductive capacity; therefore, the defect is not perpetuated in future generations. If an autosomal defect is accompanied by a total inability to reproduce, essentially all new cases of the disorder will be due to new mutations. If the defect does not affect reproductive capacity, it is more likely to be inherited.

Although there is a 50% chance of inheriting a dominant genetic disorder from an affected parent, there can be wide variation in gene penetration and expression. When a person inherits a dominant mutant gene but fails to express it, the trait is described as having reduced penetrance. Penetration is expressed in mathematical terms: a 50% penetrance indicates that a person who inherits the defective gene has a 50% chance of expressing the disorder. The person who has a mutant gene but does not express it is an important exception to the rule that unaffected persons do not transmit an autosomal dominant trait. These people can transmit the gene to their descendants and so produce a skipped generation. Autosomal dominant disorders also can display variable expressivity, meaning that they can be expressed differently among people. Polydactyly or supernumerary digits, for example, may be expressed in either the fingers or the toes.

The gene products of autosomal dominant disorders usually are regulatory proteins involved in rate-limiting components of complex metabolic pathways or key components of structural proteins such as collagen. Two disorders of autosomal inheritance, Marfan syndrome and neurofibromatosis (NF), are described in this chapter.

Marfan Syndrome. Marfan syndrome is an autosomal dominant disorder of the connective tissue, which gives shape and structure to other tissues in the body and holds them in place. The basic biochemical abnormality in Marfan syndrome affects fibrillin I, a major component of microfibrils found in the extracellular matrix. These microfibrils form the scaffold for the deposition of elastin and are considered integral components of elastic fibers. Fibrillin I is coded by the FBN1 gene, which maps to chromosome 15q21. Over 100 mutations in the FBN1 gene have been found, making genetic diagnosis

Marfan syndrome affects several organ systems, including the eyes; the cardiovascular system, specifically correlated highly with aortic aneurysms; and the skeletal system (bones and joints). There is a wide range of variation in the expression of the disorder. People may have abnormalities of one, two, or more systems. The skeletal deformities, which are the most obvious features of the disorder, include a long, thin body with exceptionally long extremities and long, tapering fingers, sometimes called arachnodactyly or spider fingers; hyperextensible joints; and a variety of spinal deformities, including kyphosis and scoliosis (Fig. 7.2). Chest deformities, pectus excavatum (i.e., deeply depressed sternum) or pigeon chest deformity, often are present and may require surgery. The most common eye disorder is bilateral dislocation of the lens due to weakness of the suspensory ligaments. Myopia and predisposition to retinal detachment also are common, the result of increased optic globe length due to altered connective tissue support of ocular structures. However, the most life-threatening aspects of the disorder are the cardiovascular defects, which include mitral valve prolapse, progressive dilation of the aortic valve ring, and weakness of the aorta and other arteries. Dissection and rupture of the aorta may lead to premature death. In women, the risk of aortic dissection is increased in pregnancy.

The diagnosis of Marfan syndrome is based on major and minor diagnostic criteria that include skeletal, cardiovascular, and ocular deformities. There is no cure for Marfan syndrome. Treatment plans include echocardiograms and electrocardiograms...
of people with NF-1, cutaneous and subcutaneous neurofibromas develop in late childhood or adolescence. The cutaneous neurofibromas, which vary in number from a few to many hundreds, manifest as soft, pedunculated lesions that project from the skin. They are the most common type of lesion, often are not apparent until puberty, and are present in greatest density over the trunk (Fig. 7.3). The subcutaneous lesions grow just below the skin. They are firm and round and may be painful. Plexiform neurofibromas involve the larger peripheral nerves. They tend to form large tumors that cause severe disfigurement of the face, overgrowth of an extremity, or skeletal deformities such as scoliosis. Pigmented nodules of the iris (Lisch nodules), which are specific for NF-1, usually are present after 6 years of age. They do not present any clinical problem but are useful in establishing a diagnosis. If a person presents with sudden visual loss and no radiological findings or increased intracranial pressure, it is a warning of possible increased tumor growth in the central nervous system (CNS).

A second major component of NF-1 is the presence of large (usually $\geq 15$ mm in diameter), flat cutaneous pigmentation, known as café au lait spots. They are usually a uniform light brown in whites and darker brown in people of color, with sharply demarcated edges. Although small single lesions may be found in normal children, larger lesions or six or more spots larger than 1.5 cm in diameter suggest NF-1. A Wood lamp, which uses ultraviolet light, can be used to detect lighter spots.

Neurofibromatosis. Neurofibromatosis is a condition that causes tumors to develop from the Schwann cells of the neurological system. There are at least two genetically and clinically distinct forms of the disorder:

1. Type 1 NF (NF-1), also known as von Recklinghausen disease
2. Type 2 bilateral acoustic NF (NF-2)

Both of these disorders result from a genetic defect in a tumor suppressor gene that regulates cell differentiation and growth. The gene for NF-1 has been mapped to the long arm of chromosome 17 and the gene for NF-2 to chromosome 22.

Type 1 NF is a common disorder, with a frequency of 1 in 4000 that affects people of all races. In more than 90% of cases, cases, it is transmitted as an autosomal dominant trait (i.e., a parent who has the condition passes it on to 50% of their children). However, 5% of cases occur as a new mutation.

The skin pigmentation becomes more evident with age as the melanosomes in the epidermal cells accumulate melanin.

Children with NF-1 are also susceptible to neurologic complications. There is an increased incidence of learning disabilities, attention deficit disorders, and abnormalities of speech among affected children. Complex partial and generalized tonic-clonic seizures are a frequent complication. Malignant neoplasms are also a significant problem in people with NF-1. One of the major complications of NF-1, occurring in 3% to 5% of people, is the appearance of a neurofibrosarcoma in a neurofibroma, usually a larger plexiform neurofibroma. NF-1 is also associated with increased incidence of other neurogenic tumors, including meningiomas, optic gliomas, and pheochromocytomas.

Type 2 NF is characterized by tumors of the acoustic nerve. Most often, the disorder is asymptomatic through the first 15 years of life. This type of NF occurs less frequently at a rate of 1 in 50,000 people. The most frequent symptoms are headaches, hearing loss, and tinnitus. There may be associated intracranial and spinal meningiomas. The condition is often made worse by pregnancy, and oral contraceptives may increase the growth and symptoms of the tumors because many neurofibromas express progesterone receptors. People with the disorder should be warned that severe disorientation may occur during diving or swimming underwater, and drowning may result. Surgery may be indicated for debulking or removal of the tumors.

Autosomal Recessive Disorders

Autosomal recessive disorders are manifested only when both members of the gene pair are affected. In this case, both parents may be unaffected but are carriers of the defective gene. Autosomal recessive disorders affect both sexes. The occurrence risks in each pregnancy are one in four for an affected child, two in four for a carrier child, and one in four for a normal (noncarrier, unaffected), homozygous child (Fig. 7.4). Consanguineous mating (mating of two related people), or inbreeding, increases the chance that two people who mate will be carriers of an autosomal recessive disorder.

With autosomal recessive disorders, the age of onset is frequently early in life. In addition, the symptomatology tends to be more uniform than with autosomal dominant disorders. Furthermore, autosomal disorders are characteristically caused by loss-of-function mutations, many of which impair or eliminate the function of an enzyme. In the case of a heterozygous carrier, the presence of a mutant gene usually does not produce symptoms because equal amounts of normal and defective enzymes are synthesized. This “margin of safety” ensures that cells with half their usual amount of enzyme function normally. By contrast, the inactivation of both alleles in a homozygote results in complete loss of enzyme activity. Autosomal recessive disorders include almost all inborn errors of metabolism. Enzyme disorders that impair catabolic pathways result in an accumulation of dietary substances (e.g., phenylketonuria [PKU]) or cellular constituents (e.g., lysosomal storage diseases). Other disorders result from a defect in the enzyme-mediated synthesis of an essential protein (e.g., the cystic fibrosis transmembrane conductance regulator in cystic fibrosis). Two examples of autosomal recessive disorders that are not covered elsewhere in this book are PKU and Tay-Sachs disease.

Phenylketonuria. PKU is a rare autosomal recessive metabolic disorder that affects approximately 1 in every 10,000 to 15,000 infants in the United States. The disorder is caused by a deficiency of the liver enzyme phenylalanine hydroxylase, which allows toxic levels of the amino acid, phenylalanine, to accumulate in tissues and the blood. If untreated, the disorder results in mental retardation, microcephaly, delayed speech, and other signs of impaired neurologic development.

Because the symptoms of PKU develop gradually and would be difficult to assess, policies have been developed to screen all infants for abnormal levels of serum phenylalanine. It is important that blood samples for PKU screening be obtained at least 24 hours after birth to ensure accuracy.

Infants with the disorder are treated with a special diet that restricts phenylalanine intake. The results of dietary therapy of children with PKU have been impressive. The diet can prevent mental retardation as well as other neurodegenerative effects of untreated PKU. However, dietary treatment must be started early in neonatal life to prevent brain damage. Infants with elevated phenylalanine levels (>10 mg/dL) should begin treatment by 7 to 10 days of age, indicating the need for early diagnosis. Evidence suggests that high levels of phenylalanine even during the first 2 weeks of life can be very harmful to the infant. Recent research regarding trials of sapropterin dihydrochloride in managing mild-to-moderate PKU shows potential promise, but more outcome data are needed.

Tay-Sachs Disease. Tay-Sachs disease is a variant of a class of lysosomal storage diseases, known as the gangliosidoses, in which there is failure to break down the GM2 gangliosides of cell membranes. Tay-Sachs disease is inherited as
an autosomal recessive trait and occurs ten times more frequently in offspring of Eastern European (Ashkenazi) Jews compared to the general population.\textsuperscript{16}

The GM2 ganglioside accumulates in the lysosomes of all organs in Tay-Sachs disease, but is most prominent in the brain neurons and retina.\textsuperscript{4} Microscopic examination reveals neurons ballooned with cytoplasmic vacuoles, each of which constitutes a markedly distended lysosome filled with gangliosides. In time, there is progressive destruction of neurons within the brain substance, including the cerebellum, basal ganglia, brain stem, spinal cord, and autonomic nervous system. Involvement of the retina is detected by ophthalmoscopy as a cherry-red spot on the macula.

Infants with Tay-Sachs disease appear normal at birth but begin to manifest progressive weakness, muscle flaccidity, and decreased attentiveness at approximately 6 to 10 months of age. This is followed by rapid deterioration of motor and mental function, often with development of generalized seizures. Retinal involvement leads to visual impairment and eventual blindness. Death usually occurs before 4 to 5 years of age. Analysis of the blood serum for the lysosomal enzyme, hexosaminidase A, which is deficient in Tay-Sachs disease, allows for accurate identification of genetic carriers for the disease. Although there is no cure for the disease, evidence suggests that the development of recombinant human lysosomal (beta)-hexosaminidase A may be helpful in assisting some people with Tay-Sachs disease to have a higher quality of life.\textsuperscript{16}

**X-Linked Recessive Disorders**

Sex-linked disorders are almost always associated with the X, or female, chromosome, and the inheritance pattern is predominantly recessive. Because of the presence of a normal paired gene, female heterozygotes rarely experience the effects of a defective gene, whereas all males who receive the gene are typically affected. The common pattern of inheritance is one in which an unaffected mother carries one normal and one mutant allele on the X chromosome. This means that she has a 50% chance of transmitting the defective gene to her sons, and her daughters have a 50% chance of being carriers of the mutant gene. The affected male passes the mutant gene to all of his daughters, who become carriers of the trait and have a 50% chance of passing the gene; her sons and her daughters have a 50% chance of being carriers of the gene (remember that their father has a normal X).

**Pathogenesis.** The fragile X gene has been mapped to the long arm of the X chromosome, designated the \textit{FMRI} (fragile X mental retardation 1) site.\textsuperscript{17} The gene product, the fragile X mental retardation protein (FMRP), is a widely expressed cytoplasmic protein. It is most abundant in the brain and testis, the organs most affected by the disorder. Each gene contains an introduction or promoter region and an instruction region that carries the directions for protein synthesis. The promoter region of the \textit{FMRI} gene contains repeats of a specific CGG (cytosine, guanine, guanine) triplet code that, when normal, controls gene activity. The mechanism by which the normal \textit{FMRI} gene is converted to an altered, or mutant, gene capable of producing disease symptoms involves an increase in the number of CGG repeats in the promoter region of the gene. Once the repeat exceeds a threshold length, no FMRP is produced, resulting in the fragile X phenotype. People without fragile X syndrome have between 6 and 40 repeats. A gene with 55 to 200 repeats is generally considered a permutation and one with more than 200 repeats, a full mutation.\textsuperscript{17}

The inheritance of the \textit{FMRI} gene follows the pattern of X-linked traits, with the father passing the gene on to all his daughters but not his sons. Approximately 20% of males who have been shown to carry the fragile X mutation are clinically and cytogenetically normal.\textsuperscript{17} Because these male carriers transmit the trait through all their daughters (who are phenotypically normal) to affected grandchildren, they are called transmitting males.

**Clinical Manifestations and Diagnosis.** Affected boys are intellectually disabled and share a common physical phenotype that includes a long face with large mandible and large, everted ears. Hypertensible joints, a high-arched palate, and mitral valve prolapse, which are observed in some cases, mimic a connective tissue disorder. Some physical abnormalities may be subtle or absent. Because girls have two
X chromosomes, they are more likely to have relatively normal cognitive development, or they may show a learning disability in a particular area, such as mathematics.

Diagnosis of fragile X syndrome is based on mental and physical characteristics. DNA molecular tests can be done to confirm the presence of an abnormal FMR1 gene. Because the manifestations of fragile X syndrome may resemble those of other learning disorders, it is recommended that people with intellectual disability of unknown cause, developmental delay, learning disorders, it is recommended that people with intellectual disability of unknown cause, developmental delay, learning disorders, or autism-like behaviors be evaluated for the disorder. Fragile X screening is now often offered along with routine prenatal screening to determine if the woman is a carrier.

**Multifactorial Inheritance Disorders**

Multifactorial inheritance disorders are caused by multiple genes and, in many cases, environmental factors. The exact number of genes contributing to multifactorial traits is not known, and these traits do not follow the same clear-cut pattern of inheritance as do single-gene disorders. Disorders of multifactorial inheritance can be expressed during fetal life and be present at birth, or they may be expressed later in life. Congenital disorders that are thought to arise through multifactorial inheritance include cleft lip or palate, clubfoot, congenital dislocation of the hip, congenital heart disease, pyloric stenosis, and urinary tract malformation. Environmental factors are thought to play a greater role in disorders of multifactorial inheritance that develop in adult life, such as coronary artery disease, diabetes mellitus, hypertension, and cancer.

Although multifactorial traits cannot be predicted with the same degree of accuracy as mendelian single-gene mutations, characteristic patterns exist. First, multifactorial congenital malformations tend to involve a single organ or tissue derived from the same embryonic developmental field. Second, the risk of recurrence in future pregnancies is for the same or a similar defect. This means that parents of a child with a cleft palate defect have an increased risk of having another child with a cleft palate, but not with spina bifida. Third, the increased risk (compared with the general population) among first-degree relatives of the affected person is 2% to 7%, and among second-degree relatives, it is approximately one half that amount. The risk increases with increasing incidence of the defect among relatives. This means that the risk is greatly increased when a second child with the defect is born to a couple. The risk also increases with severity of the disorder and when the defect occurs in the sex not usually affected by the disorder.

**Cleft Lip and Cleft Palate**

Cleft lip with or without cleft palate is one of the most common birth defects, occurring in about 0.1% of all pregnancies. It is also one of the more conspicuous birth defects, resulting in an abnormal facial appearance and defective speech. Cleft lip with or without cleft palate is more frequent among boys, whereas isolated cleft palate is twice as common among girls. The incidence of cleft palate is approximately 1 in 2500.

Developmentally, the defect has its origin at about the 35th day of gestation when the frontal prominences of the craniofacial structures fuse with the maxillary process to form the upper lip. This process is under the control of many genes, and disturbances in gene expression (hereditary or environmental) at this time may result in cleft lip with or without cleft palate (Fig. 7.6). The defect may also be caused by teratogens (e.g., rubella, anticonvulsant drugs) and is often encountered in children with chromosomal abnormalities.

Cleft lip and palate defects may vary from a small notch in the vermilion border of the upper lip to complete separation involving the palate and extending into the floor of the nose. The clefts may be unilateral or bilateral and may involve the alveolar ridge. The condition may be accompanied...
by deformed, supernumerary, or absent teeth. Isolated cleft palate occurs in the midline and may involve only the uvula or may extend into or through the soft and hard palates.

A child with cleft lip or palate may require years of special treatment by medical and dental specialists, including a plastic surgeon, pediatric dentist, orthodontist, speech therapist, and nurse specialist. The immediate problem in an infant with cleft palate is feeding. Nursing at the breast or nipple depends on suction developed by pressing the nipple against the hard palate with the tongue. Although infants with cleft lip usually have no problems with feeding, those with cleft palate usually require specially constructed, soft artificial nipples with large openings and a squeezable bottle.

Major advances in the care of children born with cleft lip and palate have occurred within the last quarter of the 20th century.18 Surgical closure of the lip is usually performed by 3 months of age, with closure of the palate usually done before 1 year of age. Depending on the extent of the defect, additional surgery may be required as the child grows. In some situations, the palate is repaired prior to the cleft lip, and results indicate that the palate surgery is easier when done prior to the cleft lip repair.19 Also the time between surgeries when cleft palate is repaired prior to lip repair is shorter.19 Displacement of the maxillary arches and malposition of the teeth usually require orthodontic correction.

Cleft lip and palate can also cause speech defects. The muscles of the soft palate and the lateral and posterior walls of the nasopharynx constitute a valve that separates the nasopharynx from the oropharynx during swallowing and in the production of certain sounds.

Chromosomal Disorders

Chromosomal disorders form a major category of genetic disease, accounting for a large proportion of reproductive wastage (early gestational abortions), congenital malformations, and intellectual disability. Cytogenetics is the term given to chromosome disorders, and they are classified using the International System for Human Cytogenetic Nomenclature.4

During cell division in non–germ cells, the chromosomes replicate so that each cell receives a full diploid number. In germ cells, a different form of division called meiosis takes place. During meiosis, the double sets of 22 autosomes and the 2 sex chromosomes (normal diploid number) are reduced to single sets (haploid number) in each gamete. At the time of conception, the haploid number in the ovum and that in the sperm join and restore the diploid number of chromosomes.

Chromosomal abnormalities are commonly described according to the shorthand description of the karyotype. In this system, the total number of chromosomes is given first, followed by the sex chromosome complement, and then the description of any abnormality. For example, a male with trisomy 21 is designated 47,XY,+21.

The aberrations underlying chromosomal disorders may take the form of alterations in the structure of one or more chromosomes or an abnormal number of chromosomes. Occasionally, mitotic errors in early development give rise to two or more cell lines characterized by distinctive karyotypes, a condition referred to as mosaicism. Mosaicism can result from mitotic errors during cleavage of the fertilized ovum or in somatic cells. Sometimes, mosaicism consists of an abnormal karyotype and a normal one, in which case the physical deformities caused by the abnormal cell line usually are less severe.

Structural Chromosomal Abnormalities

Structural changes in chromosomes usually result from breakage in one or more of the chromosomes followed by rearrangement or deletion of the chromosome parts. Among the factors believed to cause chromosome breakage are exposure to radiation sources, such as x-rays; influence of certain chemicals; extreme changes in the cellular environment; and viral infections.

Several patterns of chromosome breakage and rearrangement can occur (Fig. 7.7). There can be a deletion of the broken portion of the chromosome. When one chromosome is involved, the broken parts may be inverted. Isochromosome formation occurs when the centromere, or central portion, of the chromosome separates horizontally instead of vertically. Ring formation results when deletion is followed by uniting of the chromatids to form a ring. Translocation occurs when there are simultaneous breaks in two chromosomes from different pairs, with exchange of chromosome parts. With a balanced reciprocal translocation, no genetic information is lost; therefore, persons with translocations usually are normal. However, these people are translocation carriers and may have normal or abnormal children.

A special form of translocation called a centric fusion or robertsonian translocation involves two acrocentric chromosomes in which the centromere is near the end, most commonly chromosomes 13 and 14 or 14 and 21. Typically, the break occurs near the centromere affecting the short arm in one chromosome and the long arm in the other. Transfer of the chromosome fragments leads to one long and one extremely short fragment. The short fragment is usually lost during subsequent divisions. In this case, the person has only 45 chromosomes, but the amount of genetic material that is lost is so small that it often goes unnoticed. Difficulty, however, arises during meiosis; the result is gametes with an unbalanced number of chromosomes. The chief clinical importance of this type of translocation is that carriers of a robertsonian translocation involving chromosome 21 are at risk for producing a child with Down syndrome.

The manifestations of aberrations in chromosome structure depend to a great extent on the amount of genetic material that is lost or displaced. Many cells sustaining unresored breaks are eliminated within the next few mitoses because of deficiencies that may in themselves be fatal. This is beneficial because it prevents the damaged cells from becoming a permanent part of the organism or, if it occurs in the gametes, from giving rise to grossly defective zygotes. Some altered chromosomes, such as those that occur with translocations, are passed on to the next generation.
Having an abnormal number of chromosomes is referred to as aneuploidy. Among the causes of aneuploidy is a failure of the chromosomes to separate during oogenesis or spermatogenesis. This can occur in either the autosomes or the sex chromosomes and is called nondisjunction (Fig. 7.8). Nondisjunction gives rise to germ cells that have an even number of chromosomes (22 or 24). The products of conception formed from this even number of chromosomes have an uneven number of chromosomes, 45 or 47. 

Monosomy refers to the presence of only one member of a chromosome pair. The defects associated with monosomy of the autosomes are severe and usually cause abortion. Monosomy of the X chromosome (45,X), or Turner syndrome, causes less severe defects.

Polysomy, or the presence of more than two chromosomes to a set, occurs when a germ cell containing more than 23 chromosomes is involved in conception. Trisomy 18...
Down Syndrome. First described in 1866 by John Langdon Down, trisomy 21, or Down syndrome, causes a combination of birth defects including some degree of intellectual disability, characteristic facial features, and other health problems. It is the most common chromosomal disorder.

Approximately 95% of cases of Down syndrome are caused by nondisjunction or an error in cell division during meiosis, resulting in a trisomy of chromosome 21. A rare form of Down syndrome can occur in the offspring of people in whom there has been a robertsonian translocation (see Fig. 7.7) involving the long arm of chromosome 21q and the long arm of one of the acrocentric chromosomes (most often 14 or 22). The translocation adds to the normal long arm of chromosome 21. Therefore, the person with this type of Down syndrome has 46 chromosomes, but essentially a trisomy of 21q.4–6

The risk of having a child with Down syndrome increases with maternal age.4,20 The reason for the correlation between maternal age and nondisjunction is unknown, but is thought to reflect some aspect of aging of the oocyte. Although men continue to produce sperm throughout their reproductive life, women are born with all the oocytes they ever will have. These oocytes may change as a result of the aging process. With increasing age, there is a greater chance of a woman having been exposed to damaging environmental agents such as drugs, chemicals, and radiation. Unlike trisomy 21, Down syndrome due to a chromosome (21;14) translocation shows no relation to maternal age but has a relatively high recurrence risk in families when a parent, particularly the mother, is a carrier.

A child with Down syndrome has specific physical characteristics that are classically evident at birth.4,20 These features include a small and rather square head. There is a flat facial profile, with a small nose and somewhat depressed nasal bridge; small folds on the inner corners of the eyes (epicanthal folds) and upward slanting of the eyes; small, low-set, and malformed ears; a fat pad at the back of the neck; an open mouth; and a large, protruding tongue (Fig. 7.9). The child’s hands usually are short and stubby, with fingers that curl inward, and there usually is only a single palmar (i.e., simian) crease. There is excessive space between the large and second toes. Hypotonia and joint laxity also are present in infants and young children. There often are accompanying congenital heart defects and an increased risk of gastrointestinal malformations. Approximately 1% of people with trisomy 21 Down syndrome have mosaicism (i.e., cell populations with the normal chromosome number and trisomy 21). These people may be less severely affected. There is a high correlation of the development of acute leukemia, both myeloid and lymphoblastic, among children with Down syndrome.21 In addition, there is an increased risk of Alzheimer disease among older people with Down syndrome, and many of these children have a higher chance of acquiring cardiovascular disease.

There are several prenatal screening tests that can be done to determine the risk of having a child with Down syndrome.18 The most commonly used are blood tests that measure maternal serum levels of α-fetoprotein (AFP), human chorionic gonadotropin (hCG), unconjugated estril, inhibin A, and pregnancy-associated plasma protein A (PAPP-A) (see section on Diagnosis and Counseling). The results of three or four of these tests, together with the woman’s age, often are used to determine the probability of a pregnant woman having a child with Down syndrome. Nuchal translucency (sonolucent space on the back of the fetal neck) is another test that can be done to assess this aspect of the fetus by uses ultrasonography and can be performed between 10 and 13 weeks’ gestation.18 The fetus with Down syndrome tends to have a greater area of translucency compared with a chromosomally normal infant. The nuchal transparency test is usually used in combination with other screening tests. The only way to accurately determine the presence of Down syndrome in the fetus is through chromosome analysis using chorionic villus sampling, amniocentesis, or percutaneous umbilical blood sampling, which is discussed later in this chapter.
additional information about gene families in the so-called peculiar to the sex chromosomes: autosomes. This is related in a large part to two factors that are deletions) are much better tolerated than those involving the autosomes, although girls normally receiv...some is inactivated in females, several regions contain genes that escape inactivation and continue to be expressed by both cells of females, only one X chromosome is transcriptionally active. The other chromosome is inactive. The process of X inactivation (previously discussed in Chapter 6). In somatic cells of females, only one X chromosome is transcriptionally active. The other chromosome is inactive. The process of X inactivation, which is random, occurs early in embryonic life and is usually complete at about the end of the first week of development. After one X chromosome has become inactivated in a cell, all cells descended from that cell have the same inactivated X chromosome. Although much of one X chromosome is inactivated in females, several regions contain genes that escape inactivation and continue to be expressed by both X chromosomes. These genes may explain some of the variations in clinical symptoms seen in cases of numeric abnormalities of the X chromosome, such as Turner syndrome.

It is well known that the Y chromosome determines the male sex. The gene that dictates testicular development (Sry: sex-determining region Y gene) has been located on its distal short arm. Recent studies of the Y chromosome have yielded additional information about gene families in the so-called “male-specific Y” or MSY region. All of these are believed to be involved in spermatogenesis. A few additional genes with homologs on the X chromosome have been mapped to the Y chromosome, but to date, no disorders resulting from mutations in these genes have been described.

**Turner Syndrome.** Turner syndrome describes an absence of all (45,X/0) or part of the X chromosome. Some women with Turner syndrome may have part of the X chromosome, and some may display a mosaicism with one or more additional cells lines. This disorder affects approximately 1 of every 2500 live births and is the most frequent occurring genetic disorder in women.

Characteristically, the girl with Turner syndrome is short in stature, but her body proportions are normal (Fig. 7.10). Females with Turner syndrome lose the majority of their oocytes by the age of 2 years. Therefore, they do not menstruate and shows no signs of secondary sex characteristics. There are variations in the syndrome, with abnormalities ranging from essentially none to cardiac abnormalities such as bicuspid aortic valve and coarctation of the aorta, problems with hearing and vision, a small size mandible, a horseshoe kidney, and a small webbed neck. Women with Turner syndrome have been found to develop autoimmune disorders associated with male predominance, such as type 1 diabetes mellitus and Hashimoto thyroiditis.

---

**FIGURE 7.10**  Clinical features of Turner syndrome.

- Small stature
- Low posterior hairline and webbed neck
- Coarctation of aorta and bicuspid aortic valve
- Wide carrying angle of arms
- Retardation of bone age
- Multiple pigmented nevi
- Lymphedema of hands and feet at birth and later
- Broad chest with widely spaced nipples
- Poor breast development
- Ovarian dysgenesis with primary amenorrhea, estrogen and progesterone deficiencies, and infertility

*Remember* Jennifer, the newborn born with Down syndrome in the unit opener case study? Her disorder could have been diagnosed prenatally. Her mother was 46, which is considered advanced maternal age and associated with increased risk of aneuploidy, such as trisomy 21. The mother was offered first trimester screening at her first sonogram at 12 weeks and accepted. An increased nuchal translucency was seen on sonogram, and her trisomy 21 risk calculated from her first trimester screen indicated a 1:20 risk for trisomy 21. She declined invasive testing, such as amniocentesis, because she stated that positive results from further testing would not change her decision to continue with the pregnancy. On her anatomy sonogram and follow-up sonograms, the fetus was noted to have an absent nasal bone, echogenic bowel, short long bones, and an echogenic focus in the heart, which are all markers for possible Down syndrome. Women with abnormal first trimester screens, abnormal second trimester screens, abnormal sonogram findings, personal or family history of genetic conditions, or who are of advanced maternal age should be referred to a genetic counselor during their pregnancy for further discussion and management.

**Numeric Disorders Involving Sex Chromosomes**

Chromosomal disorders associated with the sex chromosomes are much more common than those related to the autosomes, except for trisomy 21. Furthermore, imbalances (excess or deletions) are much better tolerated than those involving the autosomes. This is related in a large part to two factors that are peculiar to the sex chromosomes:

1. The inactivation of all but one X chromosome
2. The modest amount of genetic material that is carried on the Y chromosome

Although girls normally receive both a paternal and a maternal X chromosome, the clinical manifestations of X chromosome abnormalities can be quite variable because of the process of X inactivation (previously discussed in Chapter 6). In somatic cells of females, only one X chromosome is transcriptionally active. The other chromosome is inactive. The process of X inactivation, which is random, occurs early in embryonic life and is usually complete at about the end of the first week of development. After one X chromosome has become inactivated in a cell, all cells descended from that cell have the same inactivated X chromosome. Although much of one X chromosome is inactivated in females, several regions contain genes that escape inactivation and continue to be expressed by both X chromosomes. These genes may explain some of the variations in clinical symptoms seen in cases of numeric abnormalities of the X chromosome, such as Turner syndrome.

It is well known that the Y chromosome determines the male sex. The gene that dictates testicular development (Sry: sex-determining region Y gene) has been located on its distal short arm. Recent studies of the Y chromosome have yielded additional information about gene families in the so-called
Although most women with Turner syndrome have normal intelligence, they may have problems with visuospatial organization (e.g., difficulty in driving, nonverbal problem-solving tasks such as mathematics, and psychomotor skills) and attention deficit disorders.24

The diagnosis of Turner syndrome often is delayed until late childhood or early adolescence in girls who do not present with the classic features of the syndrome. Only about 20% to 33% of affected girls receive a diagnosis as a newborn because of puffy hands and feet or redundant nuchal skin. Another 33% are diagnosed in mid-childhood because of short stature. The remainder of the girls are mainly diagnosed in adolescence when they fail to enter puberty.24 It is important to diagnose girls with Turner syndrome as early as possible so treatment plans could be implemented and managed throughout their lives.

The management of Turner syndrome begins during childhood and requires ongoing assessment and treatment. Growth hormone therapy generally can result in a gain of 6 to 10 cm in final height. Estrogen therapy, which is instituted around the normal age of puberty, is used to promote development and maintenance of secondary sexual characteristics.24

Klinefelter Syndrome. Klinefelter syndrome is a condition of testicular dysgenesis accompanied by the presence of one or more extra X chromosomes in excess of the normal male XY complement.4,25 Most males with Klinefelter syndrome have one extra X chromosome (47,XXY). In rare cases, there may be more than one extra X chromosome (48,XXXY). The presence of the extra X chromosome in the 47,XXY male results from nondisjunction during meiotic division in one of the parents. The extra X chromosome is usually of maternal origin, but approximately 1/3 of the time, it is of paternal origin. The cause of the nondisjunction is unknown. Advanced paternal age increases the risk, but only slightly. Klinefelter syndrome occurs in approximately 1 per 1000 newborn male infants.

Although the presence of the extra chromosome is fairly common, the syndrome with its accompanying signs and symptoms that may result from the extra chromosome is uncommon. Many men live their lives without being aware that they have an additional chromosome. For this reason, it has been suggested that the term Klinefelter syndrome be replaced with 47,XXY male.26

Klinefelter syndrome is characterized by enlarged breasts, sparse facial and body hair, small testes, and the inability to produce sperm25,27 (Fig. 7.11). Regardless of the number of X chromosomes present, the male phenotype is retained. The condition often goes undetected at birth. The infant usually has normal male genitalia, with a small penis and small, firm testicles. At puberty, the intrinsically abnormal testes do not respond to stimulation from the gonadotropins and undergo degeneration. This leads to a tall stature with abnormal body proportions in which the lower part of the body is longer than the upper part. Later in life, the body build may become heavy, with a female distribution of subcutaneous fat and variable degrees of breast enlargement. There may be deficient secondary male sex characteristics, such as a voice that remains feminine in pitch and sparse beard and pubic hair. Although the intellect usually is normal, most 47,XXY males have some degree of language impairment.

Adequate management of Klinefelter syndrome requires a comprehensive neurodevelopmental evaluation. In infancy and early childhood, this often includes a multidisciplinary approach to determine appropriate treatments such as physical therapy, infant stimulation programs, and speech therapy.25 Men with Klinefelter syndrome have congenital hypogonadism, which results in an inability to produce normal amounts of testosterone accompanied by an increase in hypothalamic gonadotrophic hormones. Androgen therapy is usually initiated when there is evidence of a testosterone deficit. Infertility is common in men with Klinefelter syndrome because of a decreased sperm count. If sperm are present, cryopreservation
mtDNA must exceed a critical value for a mitochondrial disease to become symptomatic. This threshold varies in different organs and is presumably related to the energy requirements of the cells.

Mitochondrial DNA mutations generally affect tissues that are dependent on oxidative phosphorylation to meet their high needs for metabolic energy. Thus, mtDNA mutations frequently affect the neuromuscular system and produce disorders such as encephalopathies, myopathies, retinal degeneration, loss of extraocular muscle function, and deafness.29,30 The range of mitochondrial diseases is broad, however, and may include liver dysfunction, bone marrow failure, and pancreatic islet cell dysfunction and diabetes, among other disorders. Table 7.2 describes representative examples of disorders due to mutations in mtDNA.

Mitochondria contain their own DNA, which is distinct from the DNA contained in the cell nucleus. There are multiple disease-affected rearrangements and point mutations. Mitochondrial DNA (mtDNA) is packaged in a double-stranded circular chromosome located inside the mitochondria.29 Mitochondrial DNA contains 37 genes: 2 ribosomal RNA (rRNA) genes, 22 transfer RNA (tRNA) genes, and 13 structural genes encoding subunits of the mitochondrial respiratory chain enzymes, which participate in oxidative phosphorylation and generation of adenosine triphosphate.4

In contrast to the mendelian pattern of inheritance of nuclear DNA, disorders of mtDNA are inherited on the maternal line. This can be explained by the fact that ova contain numerous mitochondria in their abundant cytoplasm, whereas spermatozoa contain few, if any, mitochondria. Thus, the mtDNA in the zygote is derived solely from the mother. The zygote and its daughter cells have many mitochondria, each of which contains multiple copies of the maternally derived mtDNA. During growth of the fetus or later, it is likely that some cells will contain only normal or mutant mtDNA (a situation called homoplasy), whereas others receive a mixture of normal and mutant DNA (heteroplasy). In turn, the clinical expression of a disease produced by a given mutation of mtDNA depends on the total content of mitochondrial genes and the proportion that is mutant. The fraction of mutant mtDNA must exceed a critical value for a mitochondrial disease to become symptomatic. This threshold varies in different organs and is presumably related to the energy requirements of the cells.

Mitochondrial DNA mutations generally affect tissues that are dependent on oxidative phosphorylation to meet their high needs for metabolic energy. Thus, mtDNA mutations frequently affect the neuromuscular system and produce disorders such as encephalopathies, myopathies, retinal degeneration, loss of extraocular muscle function, and deafness.29,30 The range of mitochondrial diseases is broad, however, and may include liver dysfunction, bone marrow failure, and pancreatic islet cell dysfunction and diabetes, among other disorders. Table 7.2 describes representative examples of disorders due to mutations in mtDNA.

### IN SUMMARY

Genetic disorders can affect a single gene ( mendelian inheritance) or several genes ( polygenic inheritance). Single-gene disorders may be present on an autosome or on the X chromosome, and they may be expressed as a dominant or recessive trait. In autosomal dominant disorders, a single mutant allele from an affected parent is transmitted to an offspring regardless of sex. The affected parent has a 50% chance of transmitting the disorder to each offspring. Autosomal recessive disorders are manifested only when both members of the gene pair are affected. Usually, both parents are unaffected but are carriers of the defective gene. Their chances of having an affected child are one in four; of having a carrier child, two in four; and of having a noncarrier, unaffected child, one in four. Sex-linked
disorders, which are associated with the X chromosome, are those in which an unaffected mother carries one normal and one mutant allele on the X chromosome. She has a 50% chance of transmitting the defective gene to her sons, who are affected, and her daughters have a 50% chance of being carriers of the mutant gene. Because of a normal paired gene, female heterozygotes rarely experience the effects of a defective gene. The fragile X syndrome is an inherited form of mental retardation that results from a repeating sequence of three nucleotides on a single gene in the X chromosome. Multifactorial inheritance disorders are caused by multiple genes and, in many cases, environmental factors.

Chromosomal disorders result from a change in chromosome number or structure. A change in chromosome number is called aneuploidy. Monosomy involves the presence of only one member of a chromosome pair; it is seen in Turner syndrome, in which there is monosomy of the X chromosome. Polysomy refers to the presence of more than two chromosomes in a set. Klinefelter syndrome involves polysomy of the X chromosome. Trisomy 21 (i.e., Down syndrome) is the most common form of chromosome disorder. Alterations in chromosome structure involve deletion or addition of genetic material, which may involve a translocation of genetic material from one chromosome pair to another.

The mitochondria contain their own DNA, which is distinct from nuclear DNA. This DNA, which is inherited maternally, is subject to mutations at a higher rate than nuclear DNA, and it has no repair mechanisms. Disorders of mitochondrial genes interfere with oxidative phosphorylation and the production of cellular energy. The range of mitochondrial gene disorders is diverse, with neuromuscular disorders predominating.

The developing embryo is subject to many nongenetic influences. After conception, development is influenced by the environmental factors that the embryo shares with the mother. The physiologic status of the mother—her hormone balance, her general state of health, her nutritional status, and the drugs she takes—undoubtedly influences the development of the unborn child. For example, maternal diabetes mellitus is associated with increased risk of congenital anomalies in the infant. Maternal smoking is associated with lower-than-normal neonatal weight. Maternal use of alcohol, in the context of chronic alcoholism, is known to cause fetal abnormalities. Some agents cause early abortion. Measles and other infectious agents cause congenital malformations. Other agents, such as radiation, can cause chromosomal and genetic defects and produce developmental disorders.

**Period of Vulnerability**

The embryo’s development is most easily disturbed during the period when differentiation and development of the organs are taking place. This time interval, which is often referred to as the period of organogenesis, extends from day 15 to day 60 after conception. Environmental influences during the first 2 weeks after fertilization may interfere with implantation and result in abortion or early resorption of the products of conception. Each organ has a critical period during which it is highly susceptible to environmental derangements (Fig. 7.12). Often, the effect is expressed at the biochemical level just before the organ begins to develop. The same agent may affect different organ systems that are developing at the same time.

**Teratogenic Agents**

A teratogenic agent is a chemical, physical, or biologic agent that produces abnormalities during embryonic or fetal development. Maternal disease or altered metabolic state also can affect the development of the embryo or fetus. Theoretically, teratogenic agents can cause birth defects in three ways:

1. By direct exposure of the pregnant woman and the embryo or fetus to the agent
2. Through exposure of the soon-to-be-pregnant woman to an agent that has a slow clearance rate, such that a teratogenic dose is retained during early pregnancy
3. As a result of mutagenic effects of an environmental agent that occur before pregnancy, causing permanent damage to a woman’s (or a man’s) reproductive cells

For discussion purposes, teratogenic agents have been divided into three groups: radiation, drugs and chemical substances, and infectious agents. Chart 7.1 lists commonly identified agents in each of these groups.

**Radiation**

Heavy doses of ionizing radiation are teratogenic and mutagenic and have the capacity to effect inheritable changes in genetic materials. Specifically, excessive levels of radiation have been shown to cause microcephaly, skeletal malformations, and mental retardation. There is no evidence that diagnostic levels of radiation (e.g., from a chest x-ray) cause congenital abnormalities. Additionally all efforts to shield the fetus are taken when possible. In situations where a study is
Exposure to adverse influences in the preimplantation and early postimplantation stages of development (far left) leads to prenatal death. Periods of maximal sensitivity to teratogens (horizontal bars) vary for different organ systems, but overall are limited to the first 8 weeks of pregnancy. (From Rubin R., Strayer D. S. (Eds.) (2012). Rubin’s pathology: Clinicopathologic foundations of medicine (6th ed., p. 216). Philadelphia, PA: Lippincott Williams & Wilkins.)

*Not inclusive.*
necessary for the woman’s health, the benefits to her of having proper diagnostic imaging outweigh potential theoretical risks to the fetus. Administration of therapeutic doses of radioactive iodine \[^{131}I\] during the 13th week of gestation, the time when the fetal thyroid is beginning to concentrate iodine, has been shown to interfere with thyroid development.

**Chemicals and Drugs**

Environmental chemicals and drugs can cross the placenta and cause damage to the developing embryo and fetus. It has been estimated that only 2% to 3% of developmental defects have a known drug or environmental origin. Some of the best-documented environmental teratogens are the organic mercury compounds, which cause neurologic deficits and blindness. Certain fish and water sources may be contaminated by mercury. The precise mechanisms by which chemicals and drugs exert their teratogenic effects are largely unknown. They may produce cytotoxic (cell-killing), antimitotic, or growth-inhibiting effects to the embryonic and fetal development.

Drugs top the list of chemical teratogens, probably because they are regularly used at elevated doses. Many drugs can cross the placenta and expose the fetus to both the pharmacologic and teratogenic effects. Factors that affect placental drug transfer and drug effects on the fetus include the rate at which the drug crosses the placenta, the duration of exposure, and the stage of placental and fetal development at the time of exposure. Lipid-soluble drugs tend to cross the placenta more readily and enter the fetal circulation. The molecular weight of a drug also influences the rate and amount of drug transferred across the placenta. Drugs with a molecular weight of less than 500 can cross the placenta easily, depending on lipid solubility and degree of ionization; those with a molecular weight of 500 to 1000 cross the placenta with more difficulty; and those with molecular weights of more than 1000 cross very poorly.

Several medications have been considered teratogenic. However, perhaps the best known of these drugs is thalidomide, which has been shown to give rise to a full range of malformations, including phocomelia (i.e., short, flipper-like appendages) of all four extremities. Other drugs known to cause fetal abnormalities are the antimetabolites used in the treatment of cancer, the anticonvulsant drugs phenytoin and carbamazepine, the anticoagulant drug warfarin, several of the anti-inflammatory drugs, and cocaine. Some drugs affect a single developing structure; for example, propylthiouracil can impair thyroid development and tetracycline can interfere with the mineralization phase of tooth development. More recently, vitamin A and its derivatives (the retinoids) have been targeted for concern because of their teratogenic potential. Concern over the teratogenic effects of vitamin A derivatives arose with the introduction of the acne drug isotretinoin (Accutane).

In 1983, the U.S. Food and Drug Administration established a system for classifying drugs according to probable risks to the fetus. According to this system, drugs are put into five categories: A, B, C, D, and X. Drugs in category A are the least dangerous, and categories B, C, and D are increasingly more dangerous. Those in category X are contraindicated during pregnancy because of proven teratogenicity. The law does not require classification of drugs that were in use before 1983.

Because many drugs are suspected of causing fetal abnormalities, and even those that were once thought to be safe are now being viewed critically, it is recommended that women in their childbearing years avoid unnecessary use of drugs. This pertains to nonpregnant women as well as pregnant women because many developmental defects occur early in pregnancy. As happened with thalidomide, the damage to the embryo may occur before pregnancy is suspected or confirmed. A drug that is often abused and can have deleterious effects on the fetus is alcohol.

**Fetal Alcohol Syndrome.** The term fetal alcohol syndrome (FAS) refers to a group of physical, behavioral, and cognitive fetal abnormalities that occur secondary to drinking alcohol while pregnant. It has been estimated that approximately 0.5 to 2.0 cases per 100 live births have FAS. Alcohol, which is lipid soluble and has a molecular weight between 600 and 1000, passes freely across the placental barrier. Concentrations of alcohol in the fetus are at least as high as in the mother. Unlike other teratogens, the harmful effects of alcohol are not restricted to the sensitive period of early gestation but extend throughout pregnancy.

Alcohol has widely variable effects on fetal development, ranging from minor abnormalities to FAS. There may be prenatal or postnatal growth retardation; CNS involvement, including neurologic abnormalities, developmental delays, behavioral dysfunction, intellectual impairment, and skull and brain malformation; and a characteristic set of facial features that include small palpebral fissures (i.e., eye openings), a thin vermilion border (upper lip), and an elongated, flattened midface and philtrum (i.e., the groove in the middle of the upper lip) (Fig. 7.13). The facial features of FAS may not...
be as apparent in the newborn but become more prominent as the infant develops. As the children grow into adulthood, the facial features become more subtle, making diagnosis of FAS in older people more difficult. Each of these defects can vary in severity, probably reflecting the timing of alcohol consumption in terms of the period of fetal development, amount of alcohol consumed, and hereditary and environmental influences.

The criteria for FAS diagnosis require the documented presence of three of the following findings:

1. Three facial abnormalities (smooth philtrum, thin vermilion border on the upper lip, and small palpebral fissures)
2. Growth deficits (prenatal or postnatal height or weight, or both, below the 10th percentile)
3. CNS abnormalities (e.g., head circumference below the 10th percentile, global cognitive or intellectual deficits, motor functioning delays, problems with attention or hyperactivity)

The amount of alcohol that can be safely consumed during pregnancy is unknown. Even small amounts of alcohol consumed during critical periods of fetal development may be teratogenic. For example, if alcohol is consumed during the period of organogenesis, a variety of skeletal and organ defects may result. If alcohol is consumed later in gestation, when the brain is undergoing rapid development, there may be behavioral and cognitive disorders in the absence of physical abnormalities. Chronic alcohol consumption throughout pregnancy may result in a variety of effects, ranging from physical abnormalities to growth retardation and compromised CNS functioning. Evidence suggests that short-lived high concentrations of alcohol, such as those that occur with binge drinking, may be particularly significant, with abnormalities being unique to the period of exposure. Because of the possible effect on the fetus, it is recommended that women abstain completely from alcohol during pregnancy.

**KEY POINTS**

**TERATOGENIC AGENTS**

- Teratogenic agents such as radiation, chemicals and drugs, and infectious organisms are agents that produce abnormalities in the developing embryo.
- The stage of development of the embryo determines the susceptibility to teratogens. The period during which the embryo is most susceptible to teratogenic agents is the time during which rapid differentiation and development of body organs and tissues are taking place, usually from days 15 to 60 postconception.

**Infectious Agents**

Many microorganisms cross the placenta and enter the fetal circulation, often producing multiple malformations. The acronym TORCH stands for toxoplasmosis, other, rubella (i.e., German measles), cytomegalovirus, and herpes, which are the agents most frequently implicated in fetal anomalies. Other infections include varicella–zoster virus infection, listeriosis, leptospirosis, Epstein-Barr virus infection, tuberculosis, and syphilis. Human immunodeficiency virus (HIV) and human parvovirus (B19) have been suggested as additions to the list. The TORCH screening test examines the infant’s serum for the presence of antibodies to these agents. However, the titers for serum antibodies against the TORCH agents in the mother and newborn usually are not diagnostic, and the precise cause of the disorder often remains uncertain.

Infections with the TORCH agents are reported to occur in 1% to 5% of newborn infants and are among the major causes of neonatal morbidity and mortality. Common clinical and pathologic manifestations include growth retardation and abnormalities of the brain (microcephaly, hydrocephalus), eye, ear, liver, hematopoietic system (anemia, thrombocytopenia), lungs (pneumonitis), and heart (myocarditis, congenital heart disorders). These manifestations vary among symptomatic newborns, however, and only a few present with multisystem abnormalities.

Toxoplasmosis is a protozoal infection caused by Toxoplasma gondii, which can be deleterious to pregnant woman and the unborn fetus. The domestic cat can carry the organism, excreting the protozoa in its feces. It has been suggested that pregnant women should avoid contact with excrement from the family cat. The introduction of the rubella vaccine has virtually eliminated the congenital rubella syndrome in most developed countries. Rubella remains endemic in many developing countries, however, where it is the major preventable cause of hearing impairment, blindness, and adverse neurodevelopmental outcome. The epidemiology of cytomegalovirus infection is largely unknown. Some infants are severely affected at birth, and others, although having evidence of the infection, have no symptoms. In some symptom-free infants, brain damage becomes evident over a span of several years. There also is evidence that some infants contract the infection during the first year of life, and in some of them the infection leads to retardation a year or two later. Herpes simplex virus type 2 infection is considered to be a genital infection and usually is transmitted through sexual contact. The infant acquires this infection in utero or in passage through the birth canal.

**Folic Acid Deficiency**

Although most birth defects are related to exposure to a teratogenic agent, deficiencies of nutrients and vitamins also may be a factor. Folic acid deficiency has been implicated in the development of neural tube defects (NTD) (e.g., anencephaly, spina bifida, encephalocele). Studies have shown a significant decrease in neural tube defects when folic acid was taken long term by women of reproductive age. Therefore, it is recommended that all women of childbearing age receive...
Acquiring more information from these invasive genetic tests is tantamount to the parents being aware of the potential complications of the unborn child having certain types of abnormalities. It is important to determine whether the defect was inherited and the risk of recurrence.

**Effective genetic counseling** involves accurate diagnosis and communication of the findings and of the risks of recurrence to the parents and other family members who need such information. Counseling may be provided after the birth of an affected child, or it may be offered to people at risk for having defective children (i.e., siblings of people with birth defects). A team of trained counselors can help the family to understand the problem and can support their decisions about having more children.

Assessment of genetic risk and prognosis usually is directed by a clinical geneticist, often with the aid of laboratory and clinical specialists. A detailed family history (i.e., pedigree), a pregnancy history, and detailed accounts of the birth process and postnatal health and development are included. A careful physical examination of the affected child and often of the parents and siblings usually is needed. Laboratory tests, including chromosomal analysis and biochemical studies, often precede a definitive diagnosis.

**Prenatal Screening and Diagnosis**

The purpose of prenatal screening and diagnosis is not just to detect fetal abnormalities but also to allay anxiety and provide assistance to prepare for a child with a specific disability. Prenatal screening cannot be used to rule out all possible fetal abnormalities. It is limited to determining whether the fetus has (or probably has) designated conditions indicated by late maternal age, family history, or well-defined risk factors.

There are multiple methods that can assist in diagnosing a fetus regarding genetic disorders, including ultrasonography, maternal serum (blood) screening tests, amniocentesis, chorionic villus sampling, and percutaneous umbilical fetal blood sampling (Fig. 7.14). Prenatal diagnosis can also provide the information needed for prescribing prenatal treatment for the fetus. For example, if congenital adrenal hyperplasia is diagnosed, the mother can be treated with adrenal cortical hormones to prevent masculinization of a female fetus.

**Ultrasonography**

Ultrasonography is a noninvasive diagnostic method that uses reflections of high-frequency sound waves to visualize soft tissue structures. Since its introduction in 1958, it has been used during pregnancy to determine the number of fetuses, fetal size and position, amount of amniotic fluid, and placental location. It also is possible to assess fetal movement, breathing movements, and heart pattern. There is also good evidence that early ultrasonography (i.e., before 14 weeks) accurately determines gestational age.

Improved resolution and real-time units have enhanced the ability of ultrasound scanners to detect congenital anomalies. Ultrasonography makes possible the in utero diagnosis of cardiac defects, hydrocephalus, spina bifida, facial defects, congenital heart defects, congenital diaphragmatic hernias, disorders of the gastrointestinal tract, skeletal anomalies, and various other defects. Three-dimensional (3D) sonography has become useful in better assessing facial profiles and abdominal wall defects. A fetal echocardiogram can be done as follow-up for possible cardiac anomalies. Fetal MRI
can be done to better assess skeletal, neurological, and other anomalies. Intrauterine diagnosis of congenital abnormalities permits better monitoring, further workup and planning with appropriate specialties, preterm delivery for early correction, selection of cesarean section to reduce fetal injury, and, in some cases, intrauterine therapy.

**Maternal Serum Markers**

Maternal blood testing began in the early 1980s with the test for AFP. Since that time, a number of serum factors have been studied as screening tests for fetal anomalies.

Current maternal testing favors first trimester screening for all women between 11 and 13 weeks combining nuchal translucency seen on sonogram with PAPP-A level, hCG level, and maternal age to determine a risk for trisomy 21, 13, and 18. PAPP-A, which is secreted by the placenta, has been shown to play an important role in promoting cell differentiation and proliferation in various body systems. In complicated pregnancies, the PAPP-A concentration increases with gestational age until term. Decreased PAPP-A levels in the first trimester (between 10 and 13 weeks) have been shown to be associated with Down syndrome. When used along with maternal age, free β-hCG, and ultrasonographic measurement of nuchal translucency, serum PAPP-A levels can reportedly detect 85% to 95% of affected pregnancies with a false-positive rate of approximately 5%.

A maternal serum AFP can then be done alone in the second trimester to assess for NTDs, though for pregnant women with access to good quality sonography centers, a level II ultrasound for anatomical viewing of the spine can exclude greater than 99% of spinal defects.

For pregnant women presenting too late for first trimester screening, the quad screen using AFP, hCG, inhibin A, and unconjugated estriol is used to screen for trisomy and NTDs between 15 and 22 weeks of pregnancy. The use of ultrasonography to verify fetal age can reduce the number of false-positive tests with this screening method.

AFP is a major fetal plasma protein and has a structure similar to the albumin found in postnatal life. AFP is made initially by the yolk sac, gastrointestinal tract, and liver. Fetal plasma levels of AFP peak at approximately 10 to 13 weeks’ gestation and decrease until the third trimester when the level peaks again. Maternal and amniotic fluid levels of AFP are elevated in pregnancies where the fetus has an NTD.
of the chorionic villi usually is done after 10 weeks of gestation. Performing the test before 10 weeks is not recommended because of the danger of limb reduction defects in the fetus. The chorionic villi are the site of exchange of nutrients between the maternal blood and the embryo—the chorionic sac encloses the early amniotic sac and fetus, and the villi are the primitive blood vessels that develop into the placenta. The sampling procedure can be performed using either a transabdominal or transcervical approach (see Fig. 7.14). The fetal tissue does not have to be cultured, and fetal chromosome analysis can be made available in 24 hours. DNA analysis and biochemical tests can be completed within 1 to 2 weeks.40

**Percutaneous Umbilical Cord Blood Sampling**

PUBS is an invasive diagnostic procedure that involves the transcutaneous insertion of a needle through the uterine wall and into the umbilical artery. It is performed under ultrasonographic guidance and can be done any time after 16 weeks of gestation. It is used for prenatal diagnosis of hemoglobinopathies, coagulation disorders, metabolic and cytogenetic disorders, and immunodeficiencies. Fetal infections such as rubella and toxoplasmosis can be detected through measurement of immunoglobulin M antibodies or direct blood cultures. Results from cytogenetic studies usually are available within 48 to 72 hours. Because the procedure carries a greater risk of pregnancy loss compared to amniocentesis, it usually is reserved for situations in which rapid cytogenetic analysis is needed or in which diagnostic information cannot be obtained by other methods. In the process of doing PUBS to assess fetal anemia, a blood transfusion can be administered to the fetus as needed.

**Cytogenetic and Biochemical Analyses**

Amniocentesis and chorionic villus sampling yield cells that can be used for cytogenetic and DNA analyses. Biochemical analyses can be used to detect abnormal levels of AFP and abnormal biochemical products in the maternal blood and in specimens of amniotic fluid and fetal blood.

Cytogenetic studies are used for fetal karyotyping to determine the chromosomal makeup of the fetus. They are done to detect abnormalities of chromosome number and structure. Karyotyping also reveals the sex of the fetus. This may be useful when an inherited defect is known to affect only one sex.

Analysis of DNA is done on cells extracted from the amniotic fluid, chorionic villi, or fetal blood from percutaneous umbilical sampling to detect genetic defects such as inborn errors of metabolism. The defect may be established through direct demonstration of the molecular defect or through methods that break the DNA into fragments that can be studied to determine the presence of an abnormal gene. Direct demonstration of the molecular defect is done by growing the amniotic fluid cells in culture and measuring the enzymes that the cultured cells produce. Many of the enzymes are expressed in the chorionic villi. This permits earlier prenatal diagnosis because

---

**KEY POINTS**

**DIAGNOSIS AND COUNSELING**

- Sonography, first trimester screening, quad screening, amniocentesis, chorionic villi sampling, and percutaneous umbilical cord blood sampling (PUBS) are important procedures that allow prenatal diagnosis and management.

**Amniocentesis**

Amniocentesis is an invasive diagnostic procedure that involves the withdrawal of a sample of amniotic fluid from the pregnant uterus usually using a transabdominal approach (see Fig. 7.14). The procedure is useful in women with elevated risk on first trimester screen or quad screen, abnormal fetal findings on sonogram, or in parents who are carriers or with a strong family history of an inherited disease. Ultrasonography is used to gain additional information and to guide the placement of the amniocentesis needle. The amniotic fluid and cells that have been shed by the fetus are studied. Amniocentesis can be performed on an outpatient basis starting at 15 weeks. For chromosomal analysis, the fetal cells are grown in culture and the result is available in 10 to 14 days. Beyond prenatal diagnosis, amniocentesis can also be done throughout the pregnancy as needed for testing. In cases of suspected chorioamnionitis, an amniocentesis can be done to assess for infection of the amniotic fluid. Fetal lung maturity can be assessed by amniocentesis by looking for the lecithin/sphingomyelin (L/S) ratio and presence of phosphatidylglycerol to help with delivery planning in some cases.

**Chorionic Villus Sampling**

Chorionic villus sampling is an invasive diagnostic procedure that obtains tissue that can be used for fetal chromosome studies, DNA analysis, and biochemical studies. Sampling
IN SUMMARY

Genetic and prenatal diagnosis and counseling are done in an effort to determine the risk of having a child with a genetic or chromosomal disorder. They often involve a detailed family history (i.e., pedigree), examination of any affected and other family members, and laboratory studies including chromosomal analysis and biochemical studies. They usually are done by a genetic counselor and a specially prepared team of health care professionals. Prenatal screening and diagnosis are used to detect fetal abnormalities. Ultrasonography is used for fetal anatomic imaging. It is used for determination of fetal size and position and for the presence of structural anomalies. Maternal serum screening is used to identify pregnancies that are at increased risk of adverse outcomes such as Down syndrome and NTDs. Amniocentesis and chorionic villus sampling may be used to obtain specimens for cytogenetic and biochemical studies.

REVIEW EXERCISES

1. A 23-year-old woman with sickle cell disease and her husband want to have a child but worry that the child will be born with the disease.
   A. What is the mother’s genotype in terms of the sickle cell gene? Is she heterozygous or homozygous?
   B. If the husband is found not to have the sickle cell gene, what is the probability of their child having the disease or being a carrier of the sickle cell trait?

2. A couple has a child who was born with a congenital heart disease.
   A. Would you consider the defect to be the result of a single gene or a polygenic trait?
   B. Would these parents be at greater risk of having another child with a heart defect or would they be at equal risk of having a child with a defect in another organ system, such as cleft palate?

3. A couple has been informed that their newborn child has the features of Down syndrome, and it is suggested that genetic studies be performed.
   A. The child is found to have trisomy 21. Use Figure 7.8, which describes the events that occur during meiosis, to explain the origin of the third chromosome.
   B. If the child had been found to have the robertsonian chromosome, how would you explain the origin of the abnormal chromosome?

4. An 8-year-old boy has been diagnosed with mitochondrial myopathy. His major complaints are those of muscle weakness and exercise intolerance. His mother gives a report of similar symptoms, but to a much lesser degree.
   A. Explain the cause of this boy’s symptoms.
   B. Mitochondrial disorders follow a non mendelian pattern of inheritance. Explain. Define the terms homoplasy and heteroplasmy in relation to the diversity of tissue involvement and symptoms in people with mitochondrial disorders.

5. A 26-year-old woman is planning to become pregnant.
   A. What information would you give her regarding the effects of medications and drugs on the fetus? What stage of fetal development is associated with the greatest risk?
   B. What is the rationale for ensuring that she has an adequate intake of folic acid before conception?
   C. She and her husband have an indoor cat. What precautions should she use in caring for the cat?

Cancer is the second leading cause of death in the United States. For the year 2011, it was estimated that 1,596,670 people in the United States would be newly diagnosed with cancer and 5,671,950 people would die of the disease. These numbers do not include cancer in situ or basal and squamous cell skin cancers. Approximately 11.7 million Americans alive in 2007 had a history of cancer. Trends in cancer survival demonstrate that relative 5-year survival rates have improved since the early 1990s. Although the mortality rate has decreased, the number of cancer deaths has increased due to the aging and expanding population. Cancer is not a single disease. It can originate in almost any organ, with skin cancers being the most common in the United States. Excluding skin cancers, the prostate is the most common site in men and the breast is the most common site in women. The ability to cure cancer varies considerably and depends on the type of cancer and the extent of the disease at time of diagnosis. Cancers such as Hodgkin disease, testicular cancer, and osteosarcoma, which only a few decades ago had poor prognoses, are today cured in many cases. However, lung cancer, which is the leading cause of death in men and women in the United States, is resistant to therapy, and although some progress has been made in its treatment, mortality rates remain high.

This chapter is divided into six sections:

- Concepts of cell differentiation and growth
- Characteristics of benign and malignant neoplasms
- Etiology of cancer
- Clinical manifestations
- Screening, diagnosis, and treatment
- Childhood cancers
The Cell Cycle

The cell cycle is an orderly sequence of events that occur as a cell duplicates its contents and divides (Fig. 8.1). During the cell cycle, genetic information is duplicated and the duplicated chromosomes are appropriately aligned for distribution between two genetically identical daughter cells.

The cell cycle is divided into four phases, referred to as G₁, S, G₂, and M. G₁, (gap 1) occurs after the postmitosis phase when DNA synthesis stops and ribonucleic acid (RNA) and protein synthesis and cell growth take place. During the S phase, DNA synthesis occurs, causing two separate sets of chromosomes to develop, one for each daughter cell. G₂ (gap 2) is the premitotic phase and is similar to G₁ in that DNA synthesis stops, but RNA and protein synthesis continue. The phases, G₁, S, and G₂, are referred to as interphase. The M phase is the phase of nuclear division, or mitosis, and cytoplasmic division. Continually dividing cells, such as the skin’s stratified squamous epithelium, continue to cycle from one mitotic division to the next. When environmental conditions are adverse, such as nutrient or growth factor unavailability, or when cells are highly specialized, cells may leave the cell cycle, becoming mitotically quiescent, and reside in a resting state known as G₀. Cells in G₀ may reenter the cell cycle in response to extracellular nutrients, growth factors, hormones, and other signals such as blood loss or tissue injury that trigger cell growth.

Highly specialized and terminally differentiated cells, such as neurons, may permanently stay in G₀.

Within the cell cycle, pauses can be made if the specific events of the cell cycle phases have not been completed. For
example, mitosis is prevented until DNA is properly replicated. In addition, chromosome separation in mitosis is delayed until all spindle fibers have attached to the chromosomes. These are opportunities for checking the accuracy of DNA replication. These DNA damage checkpoints allow for any defects to be identified and repaired, thereby ensuring that each daughter cell receives a full complement of genetic information, identical to that of the parent cell.2,3

The cyclins are a group of proteins that control the entry and progression of cells through the cell cycle. Cyclins bind to proteins called cyclin-dependent kinases (CDKs). Kinases are enzymes that phosphorylate proteins. The CDKs phosphorylate specific target proteins and are expressed continuously during the cell cycle but in an inactive form, whereas the cyclins are synthesized during specific phases of the cell cycle and then degraded by ubiquitination once their task is completed.4 Different arrangements of cyclins and CDKs are associated with each stage of the cell cycle (Fig. 8.2). For example, cyclin B and CDK1 control the transition from G2 to M. As the cell moves into G2, cyclin B is synthesized and binds to CDK1. The cyclin B–CDK1 complex then directs the events leading to mitosis, including DNA replication and assembly of the mitotic spindle. Although each phase of the cell cycle is monitored carefully, the transition from G2 to M is considered to be one of the most important checkpoints in the cell cycle. In addition to the synthesis and degradation of the cyclins, the cyclin–CDK complexes are regulated by the binding of CDK inhibitors (CKIs). The CKIs are particularly important in regulating cell cycle checkpoints during which mistakes in DNA replication are repaired.5 Manipulation of cyclins, CDKs, and CKIs is the basis for development of newer forms of drug therapy that can be used in cancer treatment.6

**Cell Proliferation**

Cell proliferation is the process of increasing cell numbers by mitotic cell division. In normal tissue, cell proliferation is regulated so that the number of cells actively dividing is equivalent to the number dying or being shed. In humans, there are two major categories of cells: gametes and somatic cells. The gametes (ovum and sperm) are haploid, having only one set of chromosomes from one parent, and are designed specifically for sexual fusion. After fusion, a diploid cell containing both sets of chromosomes is formed. This cell is the somatic cell that goes on to form the rest of the body.

In terms of cell proliferation, the 200 various cell types of the body can be divided into three large groups: (1) the well-differentiated neurons and cells of skeletal and cardiac muscle cells that rarely divide and reproduce; (2) the progenitor or parental cells that continue to divide and reproduce, such as blood cells, skin cells, and liver cells; and (3) the undifferentiated stem cells that can be triggered to enter the cell cycle and produce large numbers of progenitor cells if needed.2 The rates of reproduction of cells vary greatly. White blood cells and cells that line the gastrointestinal tract live several days and must be replaced constantly. In most tissues, the rate of cell reproduction is greatly increased when tissue is injured or lost. Bleeding, for example, stimulates reproduction of the blood-forming cells of the bone marrow. In some types of tissue, the genetic program for cell replication normally is suppressed but can be reactivated under certain conditions. The liver, for example, has extensive regenerative capabilities under certain conditions.

**KEY POINTS**

**CELL PROLIFERATION AND GROWTH**

- Tissue growth and repair involve cell proliferation, differentiation, and apoptosis.
- Apoptosis is a form of programmed cell death that eliminates senescent and some types of injured cells (e.g., those with DNA damage or hydrogen peroxide–induced injury).
A cell reproduces by performing an orderly sequence of events called the *cell cycle*. The cell cycle is divided into four phases of unequal duration that include the (1) synthesis (S) and mitosis (M) phases that are separated by (2) two gaps (G₁ and G₂). There is also (3) a dormant phase (G₀) during which the cell may leave the cell cycle. Movement through each of these phases is mediated at (4) specific checkpoints that are controlled by specific enzymes and proteins called *cyclins*.

**Understanding The Cell Cycle**

**Synthesis and Mitosis**

Synthesis (S) and mitosis (M) represent the two major phases of the cell cycle. The S phase, which takes about 10 to 12 hours, is the period of DNA synthesis and replication of the chromosomes. The M phase, which usually takes less than an hour, involves formation of the mitotic spindle and cell division with formation of two daughter cells.

**Gaps 1 and 2**

Because most cells require time to grow and double their mass of proteins and organelles, extra gaps (G) are inserted into the cell cycle. G₁ is the stage during which the cell is starting to prepare for DNA replication and mitosis through protein synthesis and an increase in organelle and cytoskeletal elements. G₂ is the premitotic phase. During this phase, enzymes and other proteins needed for cell division are synthesized and moved to their proper sites.
**Gap 0**

$G_0$ is the stage after mitosis during which a cell may leave the cell cycle and either remain in a state of inactivity or reenter the cell cycle at another time. Labile cells, such as blood cells and those that line the gastrointestinal tract, do not enter $G_0$ but continue cycling. Stable cells, such as hepatocytes, enter $G_0$ after mitosis but can reenter the cell cycle when stimulated by the loss of other cells. Permanent cells, such as neurons that become terminally differentiated after mitosis, leave the cell cycle and are no longer capable of cell renewal.

**Checkpoints and Cyclins**

In most cells, there are several checkpoints in the cell cycle, at which time the cycle can be arrested if previous events have not been completed. For example, the $G_1/S$ checkpoint monitors whether the DNA in the chromosomes is damaged by radiation or chemicals, and the $G_2/M$ checkpoint prevents entry into mitosis if DNA replication is not complete.

The cyclins are a family of proteins that control entry and progression of cells through the cell cycle. They function by activating proteins called CDKs. Different combinations of cyclins and CDKs are associated with each stage of the cell cycle. In addition to the synthesis and degradation of the cyclins, the cyclin–CDK complexes are regulated by the binding of CKIs. The CDK inhibitors are particularly important in regulating cell cycle checkpoints during which mistakes in DNA replication are repaired.

**Cell Differentiation**

Cell differentiation is the process whereby proliferating cells become progressively more specialized cell types. This process results in a fully differentiated, adult cell that has a specific set of structural, functional, and life expectancy characteristics. For example, the red blood cell is a terminally differentiated cell that has been programmed to develop into a concave disk, which functions as a vehicle for oxygen transport and lives approximately 3 months.

The various cell types of the body originate from a single cell—the fertilized ovum. As the embryonic cells increase in number, they engage in a coordinated process of differentiation that is necessary for the development of all the various organs of the body. The process of differentiation is regulated by a combination of internal processes involving the expression of specific genes and external stimuli provided by neighboring cells, the extracellular matrix, exposure to substances in the maternal circulation, and growth factors, cytokines, oxygen, and nutrients.
What make the cells of one organ different from those of another organ are the specific genes that are expressed and the particular pattern of gene expression. Although all cells have the same complement of genes, only a small number of these genes are expressed in postnatal life. When cells, such as those of the developing embryo, differentiate and give rise to committed cells of a particular tissue type, the appropriate genes are maintained in an active state, while the rest remain inactive. Normally, the rate of cell reproduction and the process of cell differentiation are precisely controlled in prenatal and postnatal life so that both of these mechanisms cease once the appropriate numbers and types of cells are formed.

The process of differentiation occurs in orderly steps. With each progressive step, increased specialization is exchanged for a loss of ability to develop different cell characteristics and different cell types. As a cell becomes more highly specialized, the stimuli that are able to induce mitosis become more limited. Neurons, which are highly specialized cells, lose their ability to divide and reproduce once development of the nervous system is complete. More importantly, there are very few remaining precursor cells to direct their replacement. However, appropriate numbers of these cell types are generated in the embryo that loss of a certain percentage of cells does not affect the total cell population and specific functions.

In some tissues, such as the skin and mucosal lining of the gastrointestinal tract, a high degree of cell renewal continues throughout life. Even in these continuously renewing cell populations, the more specialized cells are unable to divide. These cell populations rely on progenitor or parent cells of the same lineage that have not yet differentiated to the extent that they have lost their ability to divide. These cells are sufficiently differentiated so that their daughter cells are limited to the same cell line, but they are insufficiently differentiated to preclude the potential for active proliferation. However, their cell renewal properties are restricted by growth factors required for cell division.

Another type of cell, called a stem cell, remains incompletely differentiated throughout life. Stem cells are reserve cells that remain quiescent until there is a need for cell replenishment, in which case they divide, producing other stem cells and cells that can carry out the functions of the differentiated cell. When a stem cell divides, one daughter cell retains the stem cell characteristics, and the other daughter cell becomes a progenitor cell that proceeds through a process that leads to terminal differentiation (Fig. 8.3). The progeny of each progenitor cell follows more restricted genetic programs, with the differentiating cells undergoing multiple mitotic divisions in the process of becoming a mature cell type and with each generation of cells becoming more specialized. In this way, a single stem cell can give rise to the many cells needed for normal tissue repair or blood cell production. When the dividing cells become fully differentiated, the rate of mitotic division is reduced. In the immune system, for example, appropriately stimulated B lymphocytes become progressively more differentiated as they undergo successive mitotic divisions, until they become mature plasma cells that no longer can divide but are capable of secreting large amounts of antibody.

Stem cells have two important properties, that of self-renewal and potency. Self-renewal means that the stem cells can undergo numerous mitotic divisions while maintaining an undifferentiated state.23 The term potency is used to define the differentiation potential of stem cells. Totipotent stem cells are those produced by fertilization of the egg. The first few cells produced after fertilization are totipotent and can differentiate into embryonic and extraembryonic cells. Totipotent stem cells give rise to pluripotent stem cells that can differentiate into the three germ layers of the embryo. Multipotent stem cells are cells such as hematopoietic stem cells that give rise to only a few cell types. Finally, unipotent stem cells produce only one cell type but retain the property of self-renewal. It has become useful to categorize stem cells into two basic categories: embryonic stem cells and adult stem cells (sometimes called somatic stem cells).24 Embryonic stem cells are pluripotent cells derived from the inner cell mass of the blastocyst stage of the embryo. These give rise to the three embryonic germ cell layers. As development progresses, the embryo forms germline stem cells for reproduction and somatic stem cells for organogenesis. Both the germline stem cells and the somatic stem cells retain the property of self-renewal. Adult stem cells reside in specialized microenvironments that differ depending on tissue type. These stem cells have important roles in homeostasis as they contribute to tissue regeneration and replacement of cells lost to cell death.8

An important role of stem cells in the pathogenesis of cancer has been identified, and it continues to be studied.7–11 Cancer stem cells (called tumor-initiating cells [TICs]) have been identified in breast, prostate, acute myeloid leukemia (AML), and other cancers.12 To maintain their self-renewing properties, these stem cells express cell cycle inhibitors. There is also strong experimental support for the idea that, in certain cancers, cancer stem cells are the initial target for malignant transformation.12 If confirmed, identifying these findings could

FIGURE 8.3 • Mechanism of stem cell–mediated cell replacement. Division of a stem cell with an unlimited potential for proliferation results in one daughter cell, which retains the characteristics of a stem cell, and a second daughter cell that differentiates into a progenitor or parent cell, with a limited potential for differentiation and proliferation. As the daughter cells of the progenitor cell proliferate, they become more differentiated, until they reach the stage where they are fully differentiated.
have important implications for cancer treatment. For example, drugs can be targeted at eliminating proliferating cells.

**IN SUMMARY**

The term **neoplasm** refers to an abnormal mass of tissue in which the growth exceeds and is uncoordinated with that of the normal tissues. Unlike normal cellular adaptive processes such as hypertrophy and hyperplasia, neoplasms do not obey the laws of normal cell growth. They serve no useful purpose, they do not occur in response to an appropriate stimulus, and they continue to grow at the expense of the host.

The process of cell growth and division is called the **cell cycle**. It is divided into four phases: G1, the premitotic phase, during which protein synthesis and cell growth take place; S, the phase during which DNA synthesis occurs, giving rise to two separate sets of chromosomes; G2, the premitotic phase, during which RNA and protein synthesis continues; and M, the phase of cell mitosis or cell division. The G1 phase is a resting or quiescent phase in which nondividing cells reside. The entry into and progression through the various stages of the cell cycle are controlled by cyclins, CDKs, and CDK inhibitors.

Normal tissue renewal and repair involves cell proliferation, differentiation, and apoptosis. Proliferation, or the process of cell division, is an inherent adaptive mechanism for cell replacement when old cells die or additional cells are needed. Differentiation is the process of specialization whereby new cells acquire the structure and function of the cells they replace. Apoptosis is a form of programmed cell death that eliminates senescent cells, cells with damaged DNA, or unwanted cells. Body cells can be divided into two large groups: the well-differentiated neurons and cells of skeletal and cardiac muscle that rarely divide and reproduce, and the progenitor or parent cells that continue to divide and reproduce, such as blood cells, skin cells, and liver cells.

A third category of cells are the stem cells that remain quiescent until there is a need for cell replenishment, in which case they divide, producing other stem cells and cells that can carry out the functions of differentiated cells. Stem cells have two important properties, those of self-renewal and potency. Self-renewal means that the stem cells can undergo numerous mitotic divisions while maintaining an undifferentiated state. The term **potency** is used to define the differentiation potential of stem cells. There are two main categories of stem cells. Embryonic stem cells are pluripotent cells derived from the inner cell mass of the blastocyst stage of the embryo. Adult stem cells reside in specific microenvironments and have significant roles in homeostasis as they contribute to tissue regeneration and replacement of cells lost to apoptosis. Cancer stem cells have been identified in breast, prostate, AML, and other cancers.

**CHARACTERISTICS OF BENIGN AND MALIGNANT NEOPLASMS**

After completing this section of the chapter, you should be able to meet the following objectives:

- Relate the properties of cell differentiation to the development of a cancer cell clone and the behavior of the tumor.
- Trace the pathway for hematologic spread of a metastatic cancer cell.
- Use the concepts of growth fraction and doubling time to explain the growth of cancerous tissue.

Body organs are composed of two types of tissue: parenchymal tissue andstromal or supporting tissue. The **parenchymal tissue cells** represent the functional components of an organ. The parenchymal cells of a tumor determine its behavior and are the component for which a tumor is named. The **supporting tissue** includes the extracellular matrix and connective tissue that surround the parenchymal cells. The lymphatic and blood vessels provide nourishment and support for the parenchymal cells.

**Terminology**

Traditionally, by definition a **tumor** is a swelling that can be caused by a number of conditions, including inflammation and trauma. In addition, the term has been used to define a mass of cells that arises because of overgrowth. Although not synonymous, the terms **tumor** and **neoplasm** often are used interchangeably. Neoplasms usually are classified as benign or malignant. Neoplasms that contain well-differentiated cells that are clustered together in a single mass are considered to be **benign**. These tumors usually do not cause death unless their location or size interferes with vital functions. In contrast, **malignant neoplasms** are less well differentiated and have the ability to break loose, enter the circulatory or lymphatic system, and form secondary malignant tumors at other sites.

Tumors usually are named by adding the suffix -**oma** to the parenchymal tissue type from which the growth originated.2 Thus, a benign tumor of glandular epithelial tissue is called an **adenoma**, and a benign tumor of bone tissue is called an **osteoma**. The term **carcinoma** is used to designate a malignant tumor of epithelial tissue origin. In the case of a malignant tumor of glandular epithelial tissue, the term **adenocarcinoma** is used. Malignant tumors of mesenchymal origin are called **sarcomas** (e.g., osteosarcoma). Papillomas are benign, microscopic or macroscopic finger-like projections that grow on any surface. A **polyp** is a growth that projects from a mucosal surface, such as the intestine. Although the term usually implies a benign neoplasm, some malignant tumors also appear as polyps.2 Adenomatous polyps are considered precursors to adenocarcinomas of the colon. **Oncology** is the study of tumors and

Benign Neoplasms

Benign tumors are composed of well-differentiated cells that resemble the cells of the tissues of origin and are characterized by a slow, progressive rate of growth that may come to a standstill or regress.¹² For unknown reasons, benign tumors have lost the ability to suppress the genetic program for cell proliferation but have retained the program for normal cell differentiation. They grow by expansion and remain localized to their site of origin, lacking the capacity to infiltrate, invade, or metastasize to distant sites. Because they expand slowly, they develop a surrounding rim of compressed connective tissue called a fibrous capsule.² The capsule is responsible for a sharp line of demarcation between the benign tumor and the adjacent tissues, a factor that facilitates surgical removal.

Benign tumors are usually much less of a threat to health and well-being than malignant tumors, and they usually do not cause death unless they interfere with vital functions because of their anatomic location. For instance, a benign tumor growing in the cranial cavity can eventually cause death by compressing brain structures. Benign tumors also can cause disturbances in the function of adjacent or distant structures by producing pressure on tissues, blood vessels, or nerves. Some benign tumors are also known for their ability to cause alterations in body function by abnormally producing hormones.

**KEY POINTS**

**BENIGN AND MALIGNANT NEOPLASMS**

- A neoplasm, benign or malignant, represents a new growth.
- Benign neoplasms are well-differentiated tumors that resemble the tissues of origin but have lost the ability to control cell proliferation. They grow by expansion, are enclosed in a fibrous capsule, and do not cause death unless their location is such that it interrupts vital body functions.
- Malignant neoplasms are less well-differentiated tumors that have lost the ability to control both cell proliferation and differentiation. They grow in a disorganized and uncontrolled manner to invade surrounding tissues, have cells that break loose and travel to distant sites to form metastases, and inevitably cause suffering and death unless their growth can be controlled through treatment.

Malignant Neoplasms

Malignant neoplasms, which invade and destroy nearby tissue and spread to other parts of the body, tend to grow rapidly and spread widely and have the potential to cause death. Because of their rapid rate of growth, malignant tumors may compress blood vessels and outgrow their blood supply, causing ischemia and tissue injury. Some malignancies secrete hormones or cytokines, liberate enzymes and toxins, or induce an inflammatory response that injures normal tissue as well as the tumor itself. A number of malignancies secrete vascular endothelial cell growth factor (VEGF), which increases the blood supply to the tumor and facilitates more rapid growth.² There are two types of VEGF. VEGF-1 is used in embryonic development, but also may be present with some types of cancer metastasis. VEGF-2 is the most significant receptor associated with pathological angiogenesis and lymphangiogenesis with tumors.¹³

There are two categories of malignant neoplasms—solid tumors and hematologic cancers. Solid tumors initially are confined to a specific tissue or organ. As the growth of the primary solid tumor progresses, cells detach from the original tumor mass, invade the surrounding tissue, and enter the blood and lymph systems to spread to distant sites, a process termed metastasis (Fig. 8.4). Hematologic cancers involve cells normally found in the blood and lymph, thereby making them disseminated diseases from the beginning (Fig. 8.5).

Carcinoma in situ is a localized preinvasive lesion (Fig. 8.6). As an example, in breast ductal carcinoma in situ, the cells have not crossed the basement membrane. Depending on its location, in situ lesions usually can be removed surgically or treated so that the chances of recurrence are small. For example, carcinoma in situ of the cervix is essentially 100% curable.

**Cancer Cell Characteristics**

Cancer cells are characterized by two main features—abnormal and rapid proliferation and loss of differentiation. Loss of differentiation means that they do not exhibit normal features and properties of differentiated cells and hence are more similar to embryonic cells.

The term anaplasia describes the loss of cell differentiation in cancerous tissue.² Undifferentiated cancer cells are marked by a number of morphologic changes. Both the cells and nuclei display variations in size and shape, a condition referred to as pleomorphism. Their nuclei are variable...
The grading of tumors is based on the degree of differentiation and the number of proliferating cells. The closer the tumor cells resemble comparable normal tissue cells, both morphologically and functionally, the lower the grade. Accordingly, on a scale ranging from grades I to IV, grade I neoplasms are well differentiated and grade IV are poorly differentiated and display marked anaplasia.

In size and bizarre in shape, their chromatin is coarse and clumped, and their nucleoli are often considerably larger than normal (Fig. 8.7A). Frequently, the nuclei contain an abnormal number of chromosomes (aneuploidy). The cells of undifferentiated tumors usually display greater numbers of cells in mitosis due to their high rate of proliferation. They also display atypical, bizarre mitotic figures, sometimes producing tripolar, tetrapolar, or multipolar spindles (Fig. 8.7B). Highly anaplastic cancer cells, whatever their tissue of origin, begin to resemble undifferentiated or embryonic cells more than they do their tissue of origin. Some cancers display only slight anaplasia, whereas others display marked anaplasia. The cytologic/histologic grading of tumors is based on the degree of differentiation and the number of proliferating cells. The closer the tumor cells resemble comparable normal tissue cells, both morphologically and functionally, the lower the grade. Accordingly, on a scale ranging from grades I to IV, grade I neoplasms are well differentiated and grade IV are poorly differentiated and display marked anaplasia.²

The characteristics of altered proliferation and differen-
tiation are associated with a number of other changes in cell
characteristics and function that distinguish cancer cells from
their normally differentiated counterparts. These changes are
listed in Table 8.3.

Genetic Instability. Most cancer cells exhibit a characteristic
called genetic instability that is often considered to be a hall-
mark of cancer. The concept arose after the realization that
uncorrected mutations in normal cells are rare because of the
numerous cellular mechanisms to prevent them. To account for
the high frequency of mutations in cancer cells, it is thought that
cancer cells have a “mutation phenotype” with genetic
instability that contributes to the development and progression
of cancer. Characteristics of genetic instability include aneu-
plody, in which chromosomes are lost or gained; intrachro-
mosomal instability, which includes insertions, deletions, and
amplifications; microsatellite instability, which involves short,
repetitive sequences of DNA; and point mutations.

Growth Factor Independence. Another characteristic of
cancer cells is the ability to proliferate even in the absence of
growth factors. This characteristic is often observed when
cancer cells are propagated in cell culture—the addition of
serum, which is rich in growth factors, is unnecessary for the
cancers to proliferate. Normal cells grown in culture often die
without serum or growth factor addition. In some cases, this
is because the cancer cells can rapidly divide without growth
factor binding to its receptor. Breast cancer cells that do not
express estrogen receptors are an example. These cancer cells
grow even in the absence of estrogen, which is the normal
growth stimulus for breast duct epithelial cells. Some can-
cer cells may produce their own growth factors and secrete
them into the culture medium, whereas others have abnormal
receptors or signaling proteins that may inappropriately
activate growth signaling pathways in the cells.

Cell Density–Dependent Inhibition. Cancer cells often lose
cell density–dependent inhibition, which is the cessation of
growth after cells reach a particular density. This is sometimes
referred to as contact inhibition because cells often stop grow-
ing when they come into contact with each other. In wound heal-
ing, contact inhibition causes tissue growth to cease at the point
where the edges of the wound come together. Cancer cells, how-
ever, tend to grow rampantly without regard for adjacent tissue.
Possible explanations for cancer cell loss of density-dependent
contact inhibition include growth factor independence, oxidative
mechanisms, and alterations in interactions between cell
adhesion and cell growth signaling pathways (e.g., surface integ-
rin receptors, mitogen-activated protein [MAP] kinase, and
focal adhesion kinase [FAK] phosphorylation).

Cell Cohesiveness and Adhesion. The reduced tendency of
cancer cells to stick together (i.e., loss of cohesiveness and
adhesiveness) permits shedding of the tumor’s surface cells;
these cells appear in the surrounding body fluids or secretions
and often can be detected using cytologic methods. Cadherins
are adhesion molecules that link one cell with adjacent cells.
Extracellularly, the cadherins of one cell bind to cadherins of
adjacent cells, causing cell-to-cell attachment. Intracellularly,
cadherins are connected to the actin cytoskeleton through
protein intermediates, including the catenins. The cadherin–
catenin–actin complex, acting with other proteins, has been
proposed to be involved with cell migration, apoptosis, and
cell cycle regulation. In some cancers, the cell adhesion mol-
ecule E-cadherin appears to play an important role in the lack of
cohesiveness of cancer cells and the increased tendency for can-
cer cells to break free and migrate into the surrounding tissues.
E-cadherin is reduced at the cell surface, whereas its partner pro-
tein β-catenin accumulates within the cancer cells and associates
with the actin cytoskeletal-binding protein actinin-4. It has been
postulated that the resulting β-catenin interaction with actinin-4
in the absence of E-cadherin may be the “switch” that shuts off
cancer cell-to-cell adhesion and activates cancer cell motility and
other mechanisms that facilitate invasion and metastasis.

Anchorage Dependence. Cancer cells also differ from their nor-
mal counterparts in attaining anchorage independence. Normal
epithelial cells must be anchored to either neighboring cells or
the underlying extracellular matrix to live and grow. If normal
cells become detached, they often undergo a type of apoptosis
known as anoikis, a term from the Greek for “homeless.” Normal
epithelial cells must be attached to either other cells or extracellu-
lar matrix to stay alive. Cancer cells, however, frequently remain
viable and multiply without normal attachments to other cells
and the extracellular matrix. Cancer cells often survive in micro-
environments different from those of normal cells. Although
the process of anchorage independence is complex and incompletely
understood, recent studies have made progress in understanding
the genes and mechanistic pathways involved.
Cell-to-Cell Communication. Another characteristic of cancer cells is faulty cell-to-cell communication, a feature that may in turn contribute to other characteristics of cancer cells. Impaired cell-to-cell communication may interfere with formation of intercellular connections and responsiveness to membrane-derived signals. For example, changes in gap junction proteins, which enable cytoplasmic continuity and communication between cells, have been described in some types of cancer.19

Life Span. Cancer cells differ from normal cells by being immortal, with an unlimited life span. If normal, noncancerous cells are harvested from the body and grown under culture conditions, most cells divide a limited number of times, usually about 50 population doublings, then become senescent and fail to divide further. In contrast to the limited life span of normal cells, cancer cells may divide an infinite number of times, hence achieving immortality. Telomeres are short, repetitive nucleotide sequences at outermost extremities of chromosome arms. Telomeres shorten with each cell division. When length is diminished sufficiently, chromosomes can no longer replicate, and cell division will not occur. Most cancer cells maintain high levels of telomerase, an enzyme that prevents telomere shortening. This keeps telomeres from aging and attaining the critically short length that is associated with cellular replicative senescence.

Antigen Expression. Cancer cells also express a number of cell surface molecules or antigens that are immunologically distinct from foreign. The genes of a cell code these tissue antigens. Many transformed cancer cells revert to embryonic patterns of gene expression and produce antigens that are immunologically distinct from the antigens that are expressed by cells of the well-differentiated tissue from which the cancer originated. Some cancers express fetal antigens that are not produced by comparable cells in the adult. Tumor antigens may be clinically useful as markers to indicate the presence, recurrence, or progressive growth of a cancer.

Production of Enzymes, Hormones, and Other Substances. Cancer cells may produce substances that normal cells of the tissue of origin either do not produce or secrete in lesser amounts. They may also secrete degradative enzymes that enable invasion and metastatic spread. Cancer cells may also assume hormone synthesis or production and secretion that enable invasion and metastatic spread. For example, changes in gap junction proteins, which enable cytoplasmic continuity and communication between cells, have been described in some types of cancer.19

Cytoskeletal Changes. Finally, cancer cells may show cytoskeletal changes and abnormalities. These may involve the appearance of abnormal intermediate filament types or changes in actin filaments and microtubules that facilitate invasion and metastasis. Actin, microtubules, and their regulatory proteins remain the focus of many cancer-related investigations.

Invasion and Metastasis

Unlike benign tumors, which grow by expansion and usually are surrounded by a capsule, cancer spreads by direct invasion and extension, seeding of cancer cells in body cavities, and metastatic spread through the blood or lymph pathways. The word cancer is derived from the Latin word meaning "crablike" because cancers grow and spread by sending crablike projections into the surrounding tissues. Most cancers synthesize and secrete enzymes that break down proteins and contribute to the infiltration, invasion, and penetration of the surrounding tissues. The lack of a sharp line of demarcation separating them from the surrounding tissues makes the complete surgical removal of malignant tumors more difficult than removal of benign tumors. Often it is necessary for the surgeon to excise portions of seemingly normal tissue bordering the tumor for the pathologist to establish that cancer-free margins are present around the excised tumor and to ensure that the remaining tissue is cancer free.

The seeding of cancer cells into body cavities occurs when a tumor sheds cells into these spaces. Most often, the peritoneal cavity is involved, but other spaces such as the pleural cavity, pericardial cavity, and joint spaces may be involved. Seeding into the peritoneal cavity is particularly common with ovarian cancers. Similar to tissue culture, tumors in these sites grow in masses and are often associated with fluid accumulation (e.g., ascites, pleural effusion).2 Seeding of cancers into other areas of the body is often a complication postoperatively after removal of a cancer. The term metastasis is used to describe the development of a secondary tumor in a location distant from the primary tumor.1,3 Because metastatic tumors frequently retain many of the characteristics of the primary tumor from which they were derived, it usually is possible to determine the site of the primary tumor from the cellular characteristics of the metastatic tumor. Some tumors tend to metastasize early in their developmental course, whereas others do not metastasize until later. Occasionally, a metastatic tumor will be found far advanced before the primary tumor becomes clinically detectable. Malignant tumors of the kidney, for example, may go completely undetected and be asymptomatic until a metastatic lesion is found in the lung.

Metastasis occurs through the lymph channels (i.e., lymphatic spread) and the blood vessels (i.e., hematogenic spread).2 In many types of cancer, the first evidence of disseminated disease is the presence of tumor cells in the lymph nodes that drain the tumor area. When metastasis occurs by the lymphatic route, the tumor cells lodge first in the initial lymph node that receives drainage from the tumor site. Once in this lymph node, the cells may die because of the lack of a proper environment, grow into a discernible mass, or remain dormant for unknown reasons. If they survive and grow, the cancer cells may spread from more distant lymph nodes to the thoracic duct and then gain access to the vasculature.

The term sentinel node is used to describe the initial lymph node to which the primary tumor drains.2 Because the initial metastasis in breast cancer is almost always lymphatic, lymphatic spread and therefore extent of disease may be determined through lymphatic mapping and sentinel lymph node biopsy. This is done by injecting a radioactive tracer and/or blue dye into the tumor to determine the first lymph node in
the route of lymph drainage from the cancer. Once the sentinel lymph node has been identified, it is examined to determine the presence or absence of cancer cells. The procedure is also used to map the spread of melanoma and other cancers that have their initial metastatic spread through the lymphatic system.

With hematologic spread, the blood-borne cancer cells may enter the venous flow that drains the site of the primary neoplasm. Cancer cells may also enter tumor-associated blood vessels that either infiltrate the tumor or are found at the periphery of the tumor. Before entering the general circulation, venous blood from the gastrointestinal tract, pancreas, and spleen is routed through the portal vein to the liver. The liver is therefore a common site for metastatic spread of cancers that originate in these organs. Although the site of hematologic spread usually is related to vascular drainage of the primary tumor, some tumors metastasize to distant and unrelated sites. One explanation is that cells of different tumors tend to metastasize to specific target organs that provide suitable microenvironments containing substances such as cytokines or growth factors that are needed for their survival. For example, transferrin, a growth-promoting substance isolated from lung tissue, has been found to stimulate the growth of malignant cells that typically metastasize to the lungs. Other organs that are preferential sites for metastasis contain particular cytokines, growth factors, and other microenvironmental characteristics that facilitate metastatic tumor survival and growth.

The selective nature of hematologic spread indicates that metastasis is a finely orchestrated, multistep process, and only a small, select clone of cancer cells has the right combination of gene products to perform all of the steps needed for establishment of a secondary tumor. To metastasize, a cancer cell must be able to break loose from the primary tumor, invade the surrounding extracellular matrix, gain access to a blood vessel, survive its passage in the bloodstream, emerge from the bloodstream at a favorable location, invade the surrounding tissue, begin to grow, and establish a blood supply (Fig. 8.8). However, there is also growing evidence for the significant role of the cancer cell ecosystem—which includes, but is not limited to, the extracellular matrix, neural cells, leukocytes, endothelial cells, adipocytes, fibroblasts, and macrophages—in enabling cancer cells to establish metastatic sites (Fig. 8.9).

Considerable evidence suggests that cancer cells capable of metastasis secrete enzymes that break down the surrounding extracellular matrix, allowing them to move quickly through the degraded matrix and gain access to a blood vessel. Once in the circulation, the tumor cells are vulnerable to destruction by host immune cells. Some tumor cells gain protection from the antitumor host cells by aggregating and adhering to circulating blood components, particularly platelets, to form tumor emboli. Tumor cells that survive their travel in the circulation must be able to halt their passage by adhering to the vessel wall. Tumor cells express various cell surface attachment factors such as laminin receptors that facilitate their anchoring to laminin in the basement membrane. After attachment, the tumor cells secrete proteolytic enzymes such as type IV collagenase that degrade the basement membrane and facilitate the

---

**FIGURE 8.8** Mechanisms of tumor metastasis. Steps by which a malignant tumor penetrates basement membrane and then invades the extracellular environment. First the tumor acquires the ability to bind components of the extracellular matrix. Many adhesion molecules mediate this binding. Then proteolytic enzymes are released from the tumor cells and the extracellular matrix degrades. The invading cancer moves through the extracellular environment and then penetrates through to blood vessels and lymphatics via the same mechanisms. (From Rubin R., Strayer D. S. (Eds.) (2012). *Rubin’s pathology: Clinicopathologic foundations of medicine* (6th ed., p. 193). Philadelphia, PA: Lippincott Williams & Wilkins.)

migration of the tumor cells through the capillary membrane into the interstitial area, where they subsequently establish growth of a secondary tumor.

Once in the distant tissue site, the process of metastatic tumor development depends on the establishment of blood vessels and specific growth factors that promote proliferation of the tumor cells. Tumor cells as well as other cells in the microenvironment secrete factors that enable the development of new blood vessels within the tumor, a process termed angiogenesis. The presence of stimulatory or inhibitor growth factors correlates with the site-specific pattern of metastasis.

**Tumor Growth**

Once cells have an adequate blood supply, the rate of tissue growth in normal and cancerous tissue depends on three factors:

1. The number of cells that are actively dividing or moving through the cell cycle.
2. The duration of the cell cycle.
3. The number of cells that are being lost relative to the number of new cells being produced.

One of the reasons cancerous tumors often seem to grow so rapidly relates to the size of the cell pool that is actively engaged in cycling. It has been shown that the cell cycle time of cancerous tissue cells is not necessarily shorter than that of normal cells. Rather, cancer cells do not die on schedule and growth factors prevent cells from exiting the cycle cell and entering the G₀ phase. Thus, a greater percentage of cells are actively engaged in cycling than occurs in normal tissue.

The ratio of dividing cells to resting cells in a tissue mass is called the *growth fraction*. The *doubling time* is the length of time it takes for the total mass of cells in a tumor to double. As the growth fraction increases, the doubling time decreases. When normal tissues reach their adult size, equilibrium between cell birth and cell death is reached. Cancer cells, however, continue to divide until limitations in blood supply and nutrients inhibit their growth. When this happens, the doubling time for cancer cells decreases. If tumor growth is plotted against time on a semilogarithmic scale, the initial growth rate is exponential and then tends to decrease or flatten out over time. This characterization of tumor growth is called the *Gompertzian model* and is used for studying the effects of medications on cancer cells.

By conventional radiographic methods, a tumor usually is undetectable until it has doubled 30 times and contains more than 1 billion (10⁹) cells. At this point, it is approximately 1 cm in size. Methods to identify tumors at smaller sizes are under investigation. In some cases, the application of ultrasonography and magnetic resonance imaging (MRI) enable detection of tumors smaller than 1 cm. After 35 doublings, the mass contains more than 1 trillion (10¹²) cells, which is a sufficient number to kill the host.

**IN SUMMARY**

Neoplasms may be either benign or malignant. Benign and malignant tumors differ in terms of cell characteristics, manner of growth, rate of growth, potential for metastasis, ability to produce generalized effects, tendency to cause tissue destruction, and capacity to cause death. The growth of a benign tumor is restricted to the site of origin, and the tumor usually does not cause death unless it
interferes with vital functions. Malignant neoplasms grow in a poorly controlled fashion that lacks normal organization, spreads to distant parts of the body, and causes death unless tumor growth and metastasis are inhibited or stopped by treatment. There are two basic types of cancer: solid tumors and hematologic tumors. In solid tumors, the primary tumor is initially confined to a specific organ or tissue, whereas hematologic cancers are disseminated from the onset.

Cancer is a disorder of cell proliferation and differentiation. The term anaplasia is used to describe the loss of cell differentiation in cancerous tissue. Undifferentiated cancer cells are marked by a number of morphologic changes, including variations in size and shape, a condition referred to a pleomorphism. The characteristics of altered proliferation and differentiation are associated with a number of other changes in cell characteristics and cell function, including genetic instability; growth factor independence; loss of cell density–dependent inhibition, cohesiveness and adhesion, and anchorage dependence; faulty cell-to-cell communication; indefinite cell life span (immortality); expression of altered tissue antigens; abnormal secretion of degradative enzymes that enable invasion and metastatic spread, or ectopic production of hormones; and abnormal cytoskeletal characteristics.

The spread of cancer occurs through three pathways: direct invasion and extension, seeding of cancer cells in body cavities, and metastatic spread through vascular or lymphatic pathways. Only a proportionately small clone of cancer cells is capable of metastasis. To metastasize, a cancer cell must be able to break loose from the primary tumor, invade the surrounding extracellular matrix, gain access to a blood vessel, survive its passage in the bloodstream, emerge from the bloodstream at a favorable location, invade the surrounding tissue, and begin to grow. The rate of growth of cancerous tissue depends on the ratio of dividing to resting cells (growth fraction) and the time it takes for the total cells in the tumor to double (doubling time). A tumor is usually undetectable until it has doubled 30 times and contains more than 1 billion cells.

The causes of cancers are very diverse and complex. It is useful to discuss causation in terms of:

1. The genetic and molecular mechanisms that are involved and that characterize the transformation of normal cells to cancer cells
2. The external and more contextual factors such as age, heredity, and environmental agents that contribute to the development and progression of cancer.

Together, both mechanisms contribute to a multidimensional web of causation by which cancers develop and progress over time.

Genetic and Molecular Basis of Cancer

The molecular pathogenesis of most cancers is thought to originate with genetic damage or mutation with resultant changes in cell physiology that transform a normally functioning cell into a cancer cell. Epigenetic factors that involve silencing of a gene or genes may also be involved in the molecular pathogenesis of cancer. In recent years, an important role of cancer stem cells in the pathogenesis of cancer has been identified, and it continues to be elucidated. Finally, the cellular microenvironment, which involves multiple cell types, the complex milieu of cytokines and growth factors, and the extracellular matrix, is now recognized as an important contributor to cancer development, growth, and progression.

Cancer-Associated Genes

Most cancer-associated genes can be classified into two broad categories based on whether gene overactivity or underactivity increases the risk for cancer. The category associated with gene overactivity involves protooncogenes, which are normal genes that become cancer-causing oncogenes if mutated. Protooncogenes encode for normal cell proteins such as growth factors, growth factor receptors, growth factor signaling molecules, and transcription factors that promote cell growth or increase growth factor–dependent signaling. For example, the protooncogene, C-Myc is linked with oral squamous cell carcinoma. Increased protooncogenic activity is influenced by one’s diet, so this leads to fostering a balanced diet to attempt to decrease protooncogenic activity.21,22

The category associated with gene underactivity comprises the tumor suppressor genes, which, by being less active, create an environment in which cancer is promoted. Tumor suppressor genes include the retinoblastoma (RB) gene, which normally prevents cell division, and the TP53 gene, which normally becomes activated in DNA-damaged cells to initiate apoptosis.2,23 Loss of RB activity may accelerate the cell cycle and lead to increased cell proliferation,24 whereas inactivity of TP53 may increase the survival of DNA-damaged cells. The TP53 gene has become a reliable prognostic indicator.25 There are a number of genetic events that can lead to oncogene formation or loss of tumor suppressor gene function.
Genetic Events Leading to Oncogene Formation or Activation. There are a number of genetic events that create or activate oncogenes. A common event is a point mutation in which there is a single nucleotide base change due to an insertion, deletion, or substitution. An example of an oncogene caused by point mutations is the ras oncogene, which has been found in many cancers. Members of the ras proto-oncogene family are important signal-relaying proteins that transmit growth signals to the nucleus. Hence, activation of the ras oncogene can increase cell proliferation.

Chromosomal translocations have traditionally been associated with cancers such as Burkitt lymphoma and chronic myelogenous leukemia (CML). In Burkitt lymphoma, the myc protooncogene, which encodes a growth signal protein, is translocated from its normal position on chromosome 8 to chromosome 14 (Fig. 8.10C). The outcome of the translocation in CML is the appearance of the so-called Philadelphia chromosome involving chromosomes 9 and 22 and the formation of an abnormal fusion protein, a hybrid oncogenic protein (bcr-abl) that promotes cell proliferation (Fig. 8.10A and B). Biotechnology and genomics are enabling the identification of gene translocations and an increased understanding of how these translocations, even within the same chromosome, contribute to tumorigenesis by the creation of abnormal fusion proteins that promote cell proliferation.

Another genetic event common in cancer is gene amplification. Multiple copies of certain genes may lead to overexpression, with higher-than-normal levels of proteins that increase cell proliferation. For example, the human epidermal growth factor receptor-2 (HER-2/neu) gene is amplified in many breast cancers; its presence indicates an aggressive tumor with a poor prognosis. One of the agents used in treatment of HER-2/neu–overexpressing breast cancers is trastuzumab (Herceptin), a monoclonal antibody that selectively binds to HER-2, thereby inhibiting the proliferation of tumor cells that overexpress HER-2.

Genetic Events Leading to Loss of Tumor Suppressor Gene Function. Tumor suppressor genes inhibit the proliferation of cells in a tumor. When this type of gene is inactivated, a genetic signal that normally inhibits cell proliferation is removed, thereby causing unregulated growth to begin.

**FIGURE 8.10** • Oncogene activation by chromosomal translocation. (A) Chronic myelogenous leukemia. Reciprocal translocation occurs at the breaks at the ends of the long arms of chromosomes 9 and 22. This results in the Philadelphia chromosome (Ph1), which contains a new fusion gene coding for a hybrid oncogenic protein (bcr-abl), presumably involved in the pathogenesis of chronic myelogenous leukemia. (B) Karyotypes of a patient with CML showing the results of reciprocal translocations between chromosomes 9 and 22. The Philadelphia chromosome is recognized by a smaller-than-normal chromosome 22 (22q-). One chromosome 9 (9q+) is larger than its normal counterpart. (C) Burkitt lymphoma. Chromosomal breaks involve the long arms of chromosomes 8 and 14. The c-myc gene on chromosome 8 is translocated to a region on chromosome 14 adjacent to the gene coding for the constant region of an immunoglobulin heavy chain (C). (From Rubin R., Strayer D. S. (Eds.) (2012). Rubin’s pathology: Clinicopathologic foundations of medicine (6th ed., p. 174). Philadelphia, PA: Lippincott Williams & Wilkins.)
Multiple tumor suppressor genes have been found that connect with various types of cancer. Of particular interest in this group is the TP53 gene, which is on the short arm of chromosome 17, and codes for the p53 protein. Mutations in the TP53 gene have been associated with lung, breast, and colon cancer. The TP53 gene also appears to initiate apoptosis in radiation- and chemotherapy-damaged tumor cells.

Although a single mutation generally plays an important role in oncogene activation, the malfunction of tumor suppressor genes may require “two hits” to contribute to total loss of function, as suggested by the two-hit hypothesis of carcinogenesis (Fig. 8.11). The first “hit” may be a point mutation in an allele of a particular chromosome; later, a second “hit” occurs that involves the companion allele of the gene. In hereditary cases, the first hit is inherited from an affected parent and is therefore present in all somatic cells of the body. In RB, the second hit occurs in one of many retinal cells (all of which already carry the mutated gene). In sporadic (noninherited) cases, both mutations (hits) occur in a single somatic cell, whose progeny then form the cancer. In people carrying an inherited mutation, such as a mutated RB allele, all somatic cells are perfectly normal, except for the increased risk of developing cancer. That person is said to be heterozygous at the gene locus. Cancer develops when a person becomes homozygous for the mutant allele, a condition referred to as loss of heterozygosity which confers a poor prognosis. For example, loss of heterozygosity is known to occur in hereditary cancers, in which a mutated gene is inherited from a parent, and other conditions (e.g., radiation exposure) are present that make people more susceptible to cancer.

**Epigenetic Mechanisms**

In addition to mechanisms that involve DNA and chromosomal structural changes, there are molecular and cellular mechanisms, termed epigenetic mechanisms, which involve changes in the patterns of gene expression without a change in the DNA. Epigenetic mechanisms may “silence” genes, such as tumor suppressor genes, so that even though the gene is present, it is not expressed and a cancer-suppressing protein is not made. One such mechanism of epigenetic silencing is by methylation of the promoter region of the gene, a change that prevents transcription and causes gene inactivity. Genes silenced by hypermethylation can be inherited, and epigenetic silencing of genes could be the initial “hit” in the two-hit hypothesis described previously. The epigenetic mechanisms that alter expression of genes associated with cancer are still under investigation. The two hypomethylating agents available to treat myelodysplastic syndrome (MDS) and AML are azacitidine and decitabine.

**FIGURE 8.11** The “two-hit” origin of RB. (A) A child with an inherited form of RB is born with a germine mutation in one allele of the RB gene located on the long arm of chromosome 13. A second somatic mutation in the retina leads to inactivation of the normally functioning RB allele and subsequent development of RB. (B) In sporadic (noninherited) cases of RB, the child is born with two normal RB alleles. It requires two independent somatic mutations to inactivate RB gene function and allow for the appearance of a neoplastic clone. (From Rubin R., Strayer D. (Eds.) (2012). Rubin’s pathology: Clinicopathologic foundations of medicine (6th ed., p. 178). Philadelphia, PA: Lippincott Williams & Wilkins.)
Molecular and Cellular Pathways

There are numerous molecular and cellular mechanisms with a myriad of associated pathways and genes that are known or suspected to facilitate the development of cancer. Genes that increase susceptibility to cancer or facilitate cancer include defects in DNA repair mechanisms, defects in growth factor signaling pathways, evasion of apoptosis, avoidance of cellular senescence, development of sustained angiogenesis, and metastasis and invasion. In addition, associated genetic mutations are involved that enable invasion of and survival in neighboring tissue, as well as evasion of immune detection and attack.

DNA Repair Defects. Genetic mechanisms that regulate repair of damaged DNA have been implicated in the process of oncogenesis (Fig. 8.12). The DNA repair genes affect cell proliferation and survival indirectly through their ability to repair damage in protooncogenes, genes impacting apoptosis, and tumor suppressor genes. Genetic damage may be caused by the action of chemicals, radiation, or viruses, or it may be inherited in the germline. Significantly, it appears that the acquisition of a single-gene mutation is not sufficient to transform normal cells into cancer cells. Instead, cancerous transformation appears to require the activation of multiple independently mutated genes.

Defects in Growth Factor Signaling Pathways. A relatively common way in which cancer cells gain autonomous growth is through mutations in genes that control growth factor signaling pathways. These signaling pathways connect the growth factor receptors to their nuclear targets. Under normal conditions, cell proliferation involves the binding of a growth factor to its receptor on the cell membrane, activation of the growth factor receptor on the inner surface of the cell membrane, transfer of the signal across the cytosol to the nucleus by signal-transducing proteins that function as second messengers, induction and activation of regulatory factors that initiate DNA transcription, and entry of the cell into the cell cycle (Fig. 8.13). Many of the proteins involved in the signaling pathways that control the action of growth factors exert their effects through kinases, enzymes that phosphorylate proteins. In some types of cancer such as CML, mutation in a protooncogene controlling tyrosine kinase activity occurs, causing unregulated cell growth and proliferation.

Evasion of Apoptosis. Faulty apoptotic mechanisms have an important role in cancer. The failure of cancer cells to undergo apoptosis in a normal manner may be due to a number of problems. There may be altered cell survival signaling, overly active Ras proteins, TP53 mutations, down-regulation of death receptors (e.g., TRAIL), stabilization of the mitochondria, inactivation of proapoptotic proteins (e.g., methylation of caspase-8), overactivity of nuclear factor kappa B (NF-κB), heat-shock protein production, or failure of immune cells to induce cell death. Alterations in apoptotic and antiapoptotic pathways, genes, and proteins have been found in many cancers. One example is the high levels of the antiapoptotic protein Bcl-2 that occur secondary to a chromosomal translocation in certain B-cell lymphomas. The mitochondrial membrane is a key regulator of the balance between cell death and survival. Proteins in the Bcl-2 family reside in the inner mitochondrial membrane and are either proapoptotic or antiapoptotic. Because apoptosis is considered a normal cellular response to DNA damage, loss of normal apoptotic pathways may contribute to cancer by enabling DNA-damaged cells to survive.

Evasion of Cellular Senescence. Another normal cell response to DNA damage is cellular senescence. As stated earlier, cancer cells are characterized by immortality due to high levels of telomerase that prevent cell aging and senescence. High levels of telomerase and prevention of telomere shortening may also contribute to cancer and its progression because senescence is considered to be a normal response to DNA damage in cells as well as a tumor suppressor mechanism, and in model systems, short telomeres limit cancer growth.

Development of Sustained Angiogenesis. Even with all the aforementioned genetic abnormalities, tumors cannot enlarge unless angiogenesis occurs and supplies them with the blood

**FIGURE 8.12** Flow chart depicting the stages in the development of a malignant neoplasm resulting from exposure to an oncogenic agent that produces DNA damage. When DNA repair genes are present (red arrow), the DNA is repaired and gene mutation does not occur.
vessels necessary for survival. Angiogenesis is required not only for continued tumor growth but for metastasis. The molecular basis for the angiogenic switch is unknown, but it appears to involve increased production of angiogenic factors or loss of angiogenic inhibitors. The normal TP53 gene seems to inhibit angiogenesis by inducing the synthesis of an antiangiogenic molecule called thrombospondin-1. With mutational inactivation of both TP53 alleles (as occurs in many cancers), the levels of thrombospondin-1 drop precipitously, tilting the balance in favor of angiogenic factors. Angiogenesis is also influenced by hypoxia and release of proteases that are involved in regulating the balance between angiogenic and antiangiogenic factors. Because of the crucial role of angiogenic factor in tumor growth, bevacizumab, a monoclonal antibody, has been approved to treat metastatic colorectal and renal cell carcinomas, non–small cell lung cancer, and some brain tumors. Antiangiogenesis therapy is showing synergistic antitumor actions when combined with conventional forms of chemotherapy in the treatment of these cancers. It is being studied in other cancers as well.

Furthermore, antiangiogenesis therapy may have more broad-based actions. For example, it is now thought that cancer cells are a heterogeneous population of cells that include a cancer stem cell population characterized by mitotic quiescence and an increased ability to survive chemotherapy agents, which make cancer stem cells particularly difficult to treat. Cancer stem cells may reside close to blood vessels, where they receive signals for self-renewal.

Invasion and Metastasis. Finally, multiple genes and molecular and cellular pathways are known to be involved in invasion and metastasis. There is evidence that cancer cells with invasive properties are actually members of the cancer stem cell population discussed previously. This evidence suggests that genetic programs that are normally operative in stem cells during embryonic development may become operative in cancer stem cells, enabling them to detach, cross tissue boundaries, escape death by anoikis, and colonize new tissues. The MET protooncogene, which is expressed in both stem cells and cancer cells, is a key regulator of invasive growth. Findings suggest that adverse conditions such as tissue hypoxia, which are commonly present in cancerous tumors, trigger this invasive behavior by activating the MET tyrosine kinase receptor.

Role of the Microenvironment
Traditionally, the molecular and cellular biology of cancer has focused on the cancer itself. More recently, the important role of the microenvironment in the development of cancer and metastasis has been described. The microenvironment of the cancer cell consists of multiple cell types, including macrophages, fibroblasts, endothelial cells, and a variety of immune and inflammatory cells; the extracellular matrix; and the primary signaling substances such as cytokines, chemokines, and hormones. For example, signaling of the cytokine transforming growth factor-beta (TGF-β) is known to be important in the cellular pathway leading to cancer cell formation.
or suppression.\textsuperscript{30} The ability of TGF-\(\beta\) to cause the cancer to progress and metastasize, however, depends on the microenvironment of various cell types and cross talk of signals among the cell types. In some cases, the phenotype of a cancer cell can actually normalize when it is removed from the tumor microenvironment and placed in a normal environment, and vice versa. Finally, essential steps needed for tumor growth and metastasis, such as angiogenesis and metastatic tumor survival, depend on the microenvironment.

**Carcinogenesis**

The process by which carcinogenic (cancer-causing) agents cause normal cells to become cancer cells is hypothesized to be a multistep mechanism that can be divided into three stages: initiation, promotion, and progression (Fig. 8.14). \textit{Initiation} is the first step and describes the exposure of cells to a carcinogenic agent that causes them to be vulnerable to cancer transformation.\textsuperscript{2} The carcinogenic agents can be chemical, physical, or biologic and produce irreversible changes in the genome of a previously normal cell. Because the effects of initiating agents are irreversible, multiple divided doses may achieve the same effects as a single exposure to the same total dose or to small amounts of highly carcinogenic substances. The cells most susceptible to mutagenic alterations are those that are actively synthesizing DNA.

**Promotion** is the second step that allows for prolific growth of cells triggered by multiple growth factors and chemicals.\textsuperscript{2} Promotion is reversible if the promoter substance is removed. Cells that have been irreversibly initiated may be promoted even after long latency periods. The latency period varies with the type of agent, the dosage, and the characteristics of the target cells. Many chemical carcinogens are called \textit{complete carcinogens} because they can initiate and promote neoplastic transformation. \textit{Progression} is the last step of the process that manifests when tumor cells acquire malignant phenotypic changes that promote invasiveness, metastatic competence, autonomous growth tendencies, and increased karyotypic instability.

**Host and Environmental Factors**

Because cancer is not a single disease, it is reasonable to assume that it does not have a single cause. More likely, cancer occurs because of interactions among multiple risk factors or repeated exposure to a single carcinogenic agent. Among the traditional risk factors that have been linked to cancer are heredity, hormonal factors, immunologic mechanisms, and environmental agents such as chemicals, radiation, and cancer-causing viruses. More recently, there has been interest in obesity as a risk factor for cancer. A strong and consistent relationship has been reported between obesity and mortality from all cancers among men and women.\textsuperscript{31} Obese people tend to produce increased amounts of androgens, a portion of which is converted to the active form of estrogen in adipose tissue, causing a functional state of hyperestrogenism. Because of the association of estrogen with postmenopausal breast cancer and endometrial cancer, the relation is stronger among women than among men.\textsuperscript{31}

**Heredity**

A hereditary predisposition to approximately 50 types of cancer has been observed in families. Breast cancer, for example, occurs more frequently in women whose grandmothers, mothers, aunts, or sisters also have experienced a breast malignancy. A genetic predisposition to the development of cancer has been documented for a number of cancerous and precancerous lesions that follow mendelian inheritance patterns. Two tumor suppressor genes, called \textit{BRCA1} (breast carcinoma 1) and \textit{BRCA2} (breast carcinoma 2), have been identified in genetic lesions that follow mendelian inheritance patterns. Two tumor suppressor genes, called \textit{BRCA1} (breast carcinoma 1) and \textit{BRCA2} (breast carcinoma 2), have been identified in genetic susceptibility to breast and ovarian cancer.\textsuperscript{2} People carrying a \textit{BRCA} mutation have a lifetime risk (if they live to the age of 85 years) of 80\% for developing breast cancer. The lifetime risk for developing ovarian cancer is 10\% to 20\% for carriers of \textit{BRCA2} mutations and 40\% to 60\% for \textit{BRCA1} mutations.\textsuperscript{2} These genes have also been associated with an increased risk of prostate, pancreatic, colon, and other cancers.

Several cancers exhibit an autosomal dominant inheritance pattern that greatly increases the risk of developing a tumor.\textsuperscript{2} The inherited mutation is usually a point mutation occurring in a single allele of a tumor suppressor gene. People who inherit the mutant gene are born with one normal and one
mutant copy of the gene. For cancer to develop, the normal gene must be inactivated, usually through a somatic mutation. RB, a rare childhood tumor of the retina, is an example of a cancer that follows an autosomal dominant inheritance pattern. About 1/3 of RBs are inherited, and carriers of the mutant RB tumor suppressor gene have a significantly increased risk for developing RB, usually with bilateral involvement. Familial adenomatous polyposis of the colon also follows an autosomal dominant inheritance pattern. It is caused by mutation of another tumor suppressor gene, the APC gene. In people who inherit this gene, hundreds of adenomatous polyps may develop, and a percentage may become cancerous.

**Hormones**

Hormones have received considerable research attention with respect to cancer of the breast, ovary, and endometrium in women and of the prostate and testis in men. Although the link between hormones and the development of cancer is unclear, it has been suggested that it may reside with the ability of hormones to drive the cell division of a malignant phenotype. Because of the evidence that endogenous hormones affect the risk of these cancers, concern exists regarding the effects on cancer risk if the same or closely related hormones are administered for therapeutic purposes.

**Immunologic Mechanisms**

There is substantial evidence for the immune system’s participation in resistance against the progression and spread of cancer. The central concept, known as the immune surveillance hypothesis, first proposed in 1909, postulates that the immune system plays a central role in resistance against the development of tumors. In addition to cancer–host interactions as a mechanism of cancer development, immunologic mechanisms provide a means for the detection, classification, and prognostic evaluation of cancers and as a potential method of treatment. Immunotherapy is a cancer treatment modality designed to heighten the person’s general immune responses in order to increase tumor destruction.

It has been suggested that the development of cancer might be associated with impairment or decline in the surveillance capacity of the immune system. For example, increases in cancer incidence have been observed in people with immunodeficiency diseases and in those with organ transplants who are receiving immunosuppressant drugs. The incidence of cancer also is increased in older adults, in whom there is a known decrease in immune activity. The association of Kaposi sarcoma with acquired immunodeficiency syndrome (AIDS) further emphasizes the role of the immune system in preventing malignant cell proliferation.

It has been shown that most tumor cells have molecular configurations that can be specifically recognized by immune T cells or by antibodies and hence are termed tumor antigens. The most relevant tumor antigens fall into two categories: unique, tumor-specific antigens found only on tumor cells and tumor-associated antigens found on tumor cells and normal cells.

Virtually all of the components of the immune system have the potential for eradicating cancer cells, including T lymphocytes, B lymphocytes and antibodies, macrophages, and natural killer (NK) cells. The T-cell response is undoubtedly one of the most important host responses for controlling the growth of antigenic tumor cells. It is responsible for direct killing of tumor cells and for activation of other components of the immune system. The T-cell immunity to cancer cells reflects the function of two subsets of T cells: the CD4+ helper T cells and CD8+ cytotoxic T cells. The finding of tumor-reactive antibodies in the serum of people with cancer supports the role of the B cell as a member of the immune surveillance team. Antibodies can destroy cancer cells through complement-mediated mechanisms or through antibody-dependent cellular cytotoxicity, in which the antibody binds the cancer cell to another effector cell, such as the NK cell, that does the actual killing of the cancer cell. NK cells do not require antigen recognition and can lyse a wide variety of target cells. The cytotoxic activity of NK cells can be augmented by the cytokines interleukin (IL)-2 and interferon, and its activity can be amplified by immune T-cell responses. Macrophages are important in tumor immunity as antigen-presenting cells to initiate the immune response and as potential effector cells to participate in tumor cell lysis.

**Chemical Carcinogens**

A carcinogen is an agent capable of causing cancer. The role of environmental agents in causation of cancer was first noted in 1775, when the high incidence of scrotal cancer in chimney sweeps was identified and related to the possibility of exposure to coal soot in the chimneys. Over the next two centuries, many chemicals have been shown to transform cells in the laboratory and to be carcinogenic in animals (Chart 8.1). These agents include both natural (e.g., aflatoxin B1) and artificial products (e.g., vinyl chloride).

Chemical carcinogens can be divided into two groups: (1) direct-reacting agents, which do not require activation in the body to become carcinogenic, and (2) indirect-reacting agents, called procarcinogens or initiators, which become active only after metabolic conversion. Direct- and indirect-acting initiators form highly reactive species (i.e., electrophiles and free radicals) that bind with the nucleophilic residues on DNA, RNA, or cellular proteins. The action of these reactive species tends to cause cell mutation or alteration in synthesis of cell enzymes and structural proteins in a manner that alters cell replication and interferes with cell regulatory controls. The carcinogenicity of some chemicals is augmented by agents called promoters that, by themselves, have little or no cancer-causing ability. It is believed that promoters exert their effect by changing the expression of genetic material in a cell, increasing DNA synthesis, enhancing gene amplification (i.e., number of gene copies that are made), and altering intercellular communication.

Exposure to many chemical carcinogens is associated with lifestyle risk factors, such as smoking, dietary factors, and alcohol consumption. Cigarette smoke contains both
are produced in the combustion of tobacco and are present in cigarette smoke. Cancer of the colon has been associated with high dietary intake of fat and red meat and a low intake of dietary fiber. A high-fat diet was thought to be carcinogenic because it increases the flow of primary bile acids that are converted to secondary bile acids in the presence of anaerobic bacteria in the colon, producing carcinogens. Studies have identified obesity and lowered physical activity with an increased risk of colon cancer.31

Alcohol is associated with a variety of cancers; the causative mechanisms are very complex. The first and most toxic metabolite of ethanol is acetaldehyde that can cause point mutations in some cells.2 In addition, ethanol can alter DNA methylation and interfere with retinoid metabolism, which is important in antioxidant mechanisms. The carcinogenic effect of cigarette smoke can be enhanced by concomitant consumption of alcohol; people who smoke and drink considerable amounts of alcohol are at increased risk for development of cancer of the oral cavity, larynx, and esophagus.

The effects of carcinogenic agents usually are dose dependent—the larger the dose or the longer the duration of exposure, the greater the risk that cancer will develop. Some chemical carcinogens may act in concert with other carcinogenic influences, such as viruses or radiation, to induce neoplasia. There usually is a time delay ranging from 5 to 30 years from the time of chemical carcinogen exposure to the development of overt cancer. This is unfortunate because many people may have been exposed to the agent and its carcinogenic effects before the association was recognized. This occurred, for example, with the use of diethylstilbestrol, which was widely used in the United States from the mid-1940s to 1970 to prevent miscarriages. But it was not until the late 1960s that many cases of vaginal adenosis and adenocarcinoma in young women were found to be the result of their exposure in utero to diethylstilbestrol.38

**Radiation**

The effects of ionizing radiation in carcinogenesis have been well documented in atomic bomb survivors, in people diagnostically exposed, and in industrial workers, scientists, and physicians who were exposed during employment. Malignant epitheliomas of the skin and leukemia were significantly elevated in these populations. Between 1950 and 1970, the death rate from leukemia alone in the most heavily exposed population groups of atomic bomb survivors in Hiroshima and Nagasaki was 147 per 100,000 people, 30 times the expected rate.39

The type of cancer that developed depended on the dose of radiation, the person’s gender, and the age at which exposure occurred. For instance, approximately 25 to 30 years after total-body or trunk irradiation, there were increased incidences of leukemia and cancers of the breast, lung, stomach, thyroid, salivary gland, gastrointestinal system, and lymphoid tissues. The length of time between exposure and the onset of cancer is related to the age of the person. For example, children exposed to ionizing radiation in utero have an increased risk for developing leukemias and childhood tumors, particularly

2 to 3 years after birth. This latency period for leukemia extends to 5 to 10 years if the child was exposed after birth and to 20 years for certain solid tumors.\textsuperscript{40} As another example, the latency period for the development of thyroid cancer in infants and small children who received radiation to the head and neck to decrease the size of the tonsils or thymus was as long as 35 years after exposure.

The association between sunlight and the development of skin cancer has been reported for more than 100 years. Ultraviolet radiation consists of relatively low-energy rays that do not deeply penetrate the skin. The evidence supporting the role of ultraviolet radiation in the cause of skin cancer includes skin cancer that develops primarily on the areas of skin more frequently exposed to sunlight (\textit{e.g.}, the head and neck, arms, hands, and legs), a higher incidence in light-complexioned people who lack the ultraviolet-filtering skin pigment melanin, and the fact that the intensity of ultraviolet exposure is directly related to the incidence of skin cancer, as evidenced by higher rates occurring in Australia and the American Southwest.\textsuperscript{40} Some studies also suggest that intense, episodic exposure to sunlight, particularly during childhood, is more connected to the development of melanoma than prolonged, low-intensity exposure. As with other carcinogens, the effects of ultraviolet radiation usually are additive, and there usually is a long delay between the time of exposure and detection of the cancer.

\textbf{Oncogenic Viruses}

An oncogenic virus is one that can induce cancer. It has been suspected for some time that viruses play an important role in the development of certain forms of cancer, particularly leukemia and lymphoma. Interest in the field of viral oncology, particularly in human populations, has burgeoned with the discovery of reverse transcriptase and the development of recombinant DNA technology and, more recently, with the discovery of oncopgenes and tumor suppressor genes.

Viruses, which are small particles containing genetic material (DNA or RNA), enter a host cell and become incorporated into its chromosomal DNA, taking control of the cell’s machinery for the purpose of producing viral proteins. A large number of DNA and RNA viruses (\textit{i.e.}, retroviruses) have been shown to be oncogenic in animals. However, only a few viruses have been linked to cancer in humans.

Four DNA viruses have been identified in human cancers: the human papillomavirus (HPV), Epstein-Barr virus (EBV), hepatitis B virus (HBV), and human herpesvirus-8 (HHV-8);\textsuperscript{2} which causes Kaposi sarcoma in people with AIDS. There are over 60 genetically different types of HPV. Some types (\textit{i.e.}, types 1, 2, 4, 7) have been shown to cause benign squamous papillomas (\textit{i.e.}, warts). HPVs also have been implicated in squamous cell carcinoma of the cervix and anogenital region. HPV types 16 and 18, which are considered the most highly related to cervical cancer, and, less commonly, HPV types 31, 33, 35, and 51 are found in approximately 85% of squamous cell carcinomas of the cervix and presumed precursors (\textit{i.e.}, severe cervical dysplasia and carcinoma in situ).\textsuperscript{2}

Two vaccines to protect against specific HPV types are now available for young women and men.

EBV is a member of the herpesvirus family. It has been implicated in the pathogenesis of four human cancers: Burkitt lymphoma; nasopharyngeal cancer; B-cell lymphomas in immunosuppressed people, such as those with AIDS; and in some cases of Hodgkin lymphoma. Burkitt lymphoma, a tumor of B lymphocytes, is endemic in parts of East Africa and occurs sporadically in other areas worldwide. In people with normal immune function, the EBV-driven B cell proliferation is readily controlled and the person becomes asymptomatic or experiences a self-limited episode of infectious mononucleosis. In regions of the world where Burkitt lymphoma is endemic, concurrent malaria or other infections cause impaired immune function, allowing sustained B-lymphocyte proliferation. The incidence of nasopharyngeal cancer is high in some areas of China, particularly southern China, and in the Cantonese population in Singapore. An increased risk of B-cell lymphomas is seen in people with drug-suppressed immune systems, such as people with transplanted organs.

HBV is the etiologic agent in the development of hepatitis B, cirrhosis, and hepatocellular carcinoma. A significant correlation between elevated rates of hepatocellular carcinoma worldwide and the prevalence of HBV carriers has been found.\textsuperscript{2} Other etiologic factors also may contribute to the development of liver cancer. The precise mechanism by which HBV induces hepatocellular cancer has not been determined, although it has been suggested that it may be the result of prolonged HBV-induced liver damage and regeneration.

Although there are a number of retroviruses (RNA viruses) that cause cancer in animals, human T-cell leukemia virus-1 (HTLV-1) is the only known retrovirus to cause cancer in humans. HTLV-1 is associated with a form of T-cell leukemia that is endemic in parts of Japan and found sporadically in some other areas of the world.\textsuperscript{41} Similar to the human immunodeficiency virus (HIV) responsible for AIDS, HTLV-1 is attracted to CD4+ T cells, and this subset of T cells is therefore the major target for cancerous transformation. The virus requires transmission of infected T cells through sexual intercourse, infected blood, or breast milk.

\textbf{IN SUMMARY}

The causes of cancer are highly complex and can be viewed from two perspectives: (1) the molecular and cellular origins and mechanisms and (2) the external and contextual causative factors, including age, heredity, and environmental agents, that influence its inception and growth. In most cases, the molecular pathogenesis of cancer is thought to have its origin in genetic damage or mutation that changes cell physiology and transforms a normally functioning cell into a cancer cell. However, the complexity of the causation and pathogenesis of cancer is becoming increasingly apparent as more is learned about the roles of epigenetic mechanisms, cancer stem cells, and the microenvironment in tumorigenesis.
The types of genes involved in cancer are numerous, with the two main categories being the protooncogenes, which control cell growth and replication, and tumor suppressor genes, which are growth-inhibiting regulatory genes. Genetic and molecular mechanisms that increase susceptibility to cancer or facilitate cancer include defects in DNA repair mechanisms, defects in growth factor signaling pathways, evasion of apoptosis, development of sustained angiogenesis, and invasion and metastasis. Because cancer is not a single disease, it is likely that multiple factors interact at the molecular and cellular levels to transform normal cells into cancer cells. Genetic and epigenetic damage may be the result of interactions between multiple risk factors or repeated exposure to a single carcinogen. Among the risk factors that have been linked to cancer are heredity, hormonal factors, immunologic mechanisms, and environmental agents such as chemicals, radiation, and cancer-causing viruses.

CLINICAL MANIFESTATIONS

After completing this section of the chapter, you should be able to meet the following objectives:

- Characterize the mechanisms involved in the anorexia and cachexia, fatigue and sleep disorders, anemia, and venous thrombosis experienced by people with cancer.
- Define the term paraneoplastic syndrome and explain its pathogenesis and manifestations.

There probably is not a single body function left unaffected by the presence of cancer. Because tumor cells replace normally functioning parenchymal tissue, the initial manifestations of cancer usually reflect the primary site of involvement. For example, cancer of the lung initially produces impairment of respiratory function; as the tumor grows and metastasizes, other body structures become affected. Cancer also produces generalized manifestations such as fatigue, anorexia and cachexia, anemia, decreased resistance to infections, and symptoms unrelated to the tumor site (paraneoplastic syndromes). Many of these manifestations are compounded by the side effects of methods used to treat the disease. In its late stages, cancer often causes pain. Pain is one of the most dreaded aspects of cancer, and pain management is one of the major treatment concerns for persons with incurable cancers.

Tissue Integrity

Cancer disrupts tissue integrity. As cancers grow, they compress and erode blood vessels, causing ulceration and necrosis along with frank bleeding and sometimes hemorrhage. One of the early warning signals of colorectal cancer is blood in the stool. Cancer cells also may produce enzymes and metabolic toxins that are destructive to the surrounding tissues. Usually, tissue damaged by cancerous growth does not heal normally. Instead, the damaged area persists and often continues to grow; a sore that does not heal is another warning signal of cancer. Cancer has no regard for normal anatomic boundaries; as it grows, it invades and compresses adjacent structures. Abdominal cancer, for example, may compress the viscera and cause bowel obstruction.

The development of effusions or fluid in the pleural, pericardial, or peritoneal spaces is often the presenting sign of some tumors. Direct involvement of the serous surface seems to be the most significant inciting factor, although many other mechanisms, such as obstruction of lymphatic flow, may play a role. It has been reported that almost 50% of undiagnosed effusions in people not known to have cancer turn out to be due to malignancy. Lung cancers, breast cancers, and lymphomas account for about 75% of malignant pleural effusions. Most people with pleural effusions are symptomatic at presentation, with chest pain, shortness of breath, and cough. More than any other malignant neoplasms, ovarian cancers are associated with the accumulation of fluid in the peritoneal cavity. Abdominal discomfort, swelling and a feeling of heaviness, and increase in abdominal girth, which reflect the presence of peritoneal effusions or ascites, shortness of breath, and difficulty breathing are common presenting symptoms in ovarian cancer.

Systemic Manifestations

Many of the clinical manifestations of cancer, including anorexia and cachexia, fatigue and sleep disorders, and anemia, are not directly related to the presence of a tumor mass but to altered metabolic pathways and the presence of circulating cytokines and other mediators. Although research has produced amazing insights into the causes and cures for cancer, much still is needed regarding management of the associated side effects of the disease.

Anorexia and Cachexia

Many cancers are associated with weight loss and wasting of body fat and muscle tissue, accompanied by profound weakness, anorexia, and anemia. This wasting syndrome is often referred to as the cancer anorexia–cachexia syndrome. It is a common manifestation of most solid tumors, with the exception of breast cancer. It has been estimated that it is a significant cause of morbidity and mortality in 80% of people with advanced cancer and is responsible for death in up to 20% of cases. The condition is more common in children and older adults and becomes more pronounced as the disease progresses. People with cancer cachexia also respond less well to chemotherapy and are more prone to toxic side effects.

Although anorexia, reduced food intake, and abnormalities of taste are common in people with cancer and often are accentuated by treatment methods, the extent of weight loss and protein wasting cannot be explained in terms of diminished food intake alone. In contrast to starvation due to lack of
food intake, where weight is preferentially lost from the fat compartment, in cachexia, it is lost from both the fat and skeletal muscle compartments. Furthermore, the protein loss that occurs with starvation is divided equally between skeletal muscle and visceral proteins, whereas in cachexia, visceral proteins are relatively well preserved. Thus, there is a loss of liver mass in starvation, but an increase in cachectic people because of hepatic recycling of nutrients and the acute-phase response. Finally, and more important, weight loss that occurs with starvation is usually reversed by refeeding, whereas oral or parenteral nutritional supplementation does not reverse cachexia.

The mechanisms of cancer cachexia appear to reside in a hypermetabolic state and altered nutrient metabolism that are specific to the tumor-bearing state. Tumors tend to consume large amounts of glucose, with a resultant increase in lactate formation because the tumor oxygen levels are too low to support the citric acid cycle and mitochondrial oxidative phosphorylation. The lactate that is produced then circulates to the liver, where it is converted back to glucose. The production of glucose (gluconeogenesis) from lactate uses adenosine triphosphate (ATP) and is very energy inefficient, contributing to the hypermetabolic state of cachectic people. Another mechanism for the increasing energy expenditure in cachectic people is the increased expression of mitochondrial uncoupling proteins that uncouple the oxidative phosphorylation process, so that energy is lost as heat. Abnormalities in fat and protein metabolism have also been reported. During starvation in people without cancer, ketones derived from fat replace the glucose normally used by the brain, leading to decreased gluconeogenesis from amino acids with conservation of muscle mass, whereas in people with cancer cachexia, amino acids are not spared and there is depletion of lean body mass, a condition thought to contribute to decreased survival time.

Although the mechanisms of the cancer anorexia–cachexia syndrome remain incompletely understood, they are probably multifactorial, resulting from a persistent inflammatory response in conjunction with production of specific cytokines and catabolic factors by the tumor. The syndrome shows similarities to that of the acute-phase response seen with tissue injury, infection, or inflammation, in which liver protein synthesis changes from synthesis of albumin to acute-phase proteins such as C-reactive protein, fibrinogen, and α1-antitrypsin. The acute-phase response is known to be activated by cytokines such as tumor necrosis factor-α (TNF-α) and IL-1 and IL-6, suggesting that they may also play a role in cancer cachexia. High serum levels of these cytokines have been observed in people with cancer, and their levels appear to correlate with progression of the tumor. TNF-α, secreted primarily by macrophages in response to tumor cell growth or gram-negative bacterial infections, was the first cytokine associated with cachexia and wasting to be identified. It causes anorexia by suppressing satiety centers in the hypothalamus and increasing the synthesis of lipoprotein lipase, an enzyme that facilitates the release of fatty acids from lipoproteins so that they can be used by tissues. IL-1 and IL-6 share many of the features of TNF-α in terms of the ability to initiate cachexia.

**Fatigue and Sleep Disorders**

Fatigue and sleep disturbances are two of the most frequent side effects experienced by people with cancer. Cancer-related fatigue is characterized by feelings of tiredness, weakness, and lack of energy and is distinct from the normal tiredness experienced by healthy people in that it is not relieved by rest or sleep. It occurs both as a consequence of the cancer itself and as a side effect of cancer treatment. Cancer-related fatigue may be an early symptom of malignant disease and has been reported by more than a third of people at the time of diagnosis. Furthermore, the symptom often remains for months or even years after treatment.

The cause of cancer-related fatigue is largely unknown, but is probably multifactorial and involves the dysregulation of several interrelated physiologic, biochemical, and psychological systems. The basic mechanisms of fatigue have been broadly categorized into two components: peripheral and central. Peripheral fatigue, which occurs in the neuromuscular junctions and muscles, results from the inability of the peripheral neuromuscular apparatus to perform a task in response to central stimulation. Mechanisms implicated in peripheral fatigue include a lack of ATP and the buildup of metabolic by-products such as lactic acid. Central fatigue arises in the central nervous system (CNS) and is often described as difficulty in initiating or maintaining voluntary activities. One hypothesis proposed to explain cancer-related fatigue is that cancer and cancer treatments result in dysregulation of brain serotonin (5-hydroxytryptamine [5-HT]) levels or function. There is evidence that proinflammatory cytokines, such as TNF-α, can influence 5-HT metabolism.

Although cancer-related fatigue and sleep disorders are distinct conditions, they are closely linked in terms of prevalence and symptoms. People with cancer report poor sleep quality, disturbed initiation and maintenance of sleep, insufficient sleep, nighttime awakening, and restless sleep. As with fatigue, precipitating factors include the diagnosis of cancer, type and stage of cancer, pain, and side effects of treatment (e.g., nausea, vomiting). Once it begins, insomnia is often self-perpetuating because of the natural tendency to compensate for sleep loss by napping, going to bed earlier, and getting out of bed later. It may also be that the fatigue that occurs with cancer or anticancer therapy may, in fact, prompt people to extend their sleep opportunity and thus becomes a contributing factor to ongoing insomnia. Correlations have also been noted between fatigue and daytime symptoms of sleep problems, such as daytime sleepiness and napping.

**Anemia**

Anemia is common in people with various types of cancers. It may be related to blood loss, hemolysis, impaired red blood cell production, or treatment effects. For example, drugs used in treatment of cancer are cytotoxic and can decrease red blood cell production. Also, there are many mechanisms through which erythrocyte production can be impaired in people with malignancies, including nutritional deficiencies, bone marrow failure, and a blunted erythropoietin response.
to hypoxia. Inflammatory cytokines generated in response to tumors decrease erythropoietin production, resulting in a decrease in erythrocyte production.

Cancer-related anemia is associated with reduced treatment effectiveness, increased mortality, increased transfusion requirements, and reduced performance and quality of life. Hypoxia, a characteristic feature of advanced solid tumors, has been recognized as a critical factor in promoting tumor resistance to radiation therapy and some chemotherapeutic agents. Severe anemia may delay surgical interventions when preoperative transfusions are required. Similarly, low hemoglobin levels before or during chemotherapy may require dose reductions or delays in administration, resulting in a decrease in overall treatment effectiveness. Cancer-related anemia is often treated with recombinant human erythropoietin.

**Paraneoplastic Syndromes**

In addition to signs and symptoms at the sites of primary and metastatic disease, cancer can produce manifestations in sites that are not directly affected by the disease. Such manifestations are collectively referred to as *paraneoplastic syndromes.* Some of these manifestations are caused by the elaboration of hormones by cancer cells, and others from the production of circulating factors that produce hematopoietic, neurologic, and dermatologic syndromes (Table 8.4). These syndromes are most commonly associated with lung, breast, and hematologic malignancies.

A variety of peptide hormones are produced by both benign and malignant tumors. Although not normally expressed, the biochemical pathways for the synthesis and release of peptide hormones (e.g., antidiuretic [ADH], adrenocorticotropic [ACTH], and parathyroid [PTH] hormones) are in most cells. Thus, the three most common endocrine syndromes associated with cancer are the syndrome of inappropriate ADH secretion, Cushing syndrome due to ectopic ACTH production, and hypercalcemia. Hypercalcemia of malignancy does not appear to be related to PTH but to a PTH-related protein that shares several biologic actions with PTH. Hypercalcemia also can be caused by cancers such as multiple myeloma or bony metastases from other cancers.

Some paraneoplastic syndromes are associated with the production of circulating mediators that produce hematologic complications. For example, a variety of cancers may produce procoagulation factors that contribute to an increased risk for venous thrombosis and nonbacterial thrombotic endocarditis. Sometimes, unexplained thrombotic events are the first indication of an undiagnosed malignancy. The precise relationship

between coagulation disorders and cancer is still unknown. Several malignancies, such as mucin-producing adenocarcinomas, release thromboplastin and other substances that activate the clotting system.

The symptomatic paraneoplastic neurologic disorders are relatively rare, with the exception of the Lambert-Eaton myasthenic syndrome, which affects about 3% of people with small cell lung cancer, and myasthenia gravis, which affects about 15% of people with thymoma. The Lambert-Eaton syndrome, or reverse myasthenia gravis, is seen almost exclusively in small cell lung cancer. It produces muscle weakness in the limbs rather than the initial bulbar and ocular muscle weakness seen in myasthenia gravis. The origin of paraneoplastic neurologic disorders is thought to be immune mediated. The altered immune response is initiated by the production of onconeural antigens (e.g., antigens normally expressed in the nervous system) by the cancer cells. The immune system, in turn, recognizes the onconeural antigens as foreign and mounts an immune response. In many cases, the immune attack controls the growth of the cancer. The antibodies and cytotoxic T cells are not sufficient to cause neurologic disease unless they cross the blood–brain barrier and react with neurons expressing the onconeural antigen.

A wide variety of cutaneous syndromes are associated with malignancies and may precede, be concurrent with, or follow the discovery of cancer. Among the paraneoplastic dermatologic disorders is acanthosis nigricans, characterized by pigmented hyperkeratoses consisting of symmetric, verrucose, and papillary lesions that occur in skin flexures, particularly the axillary and perineal areas. The lesions are usually symmetric and may be accompanied by pruritus. The condition is usually associated with adenocarcinomas of the gastrointestinal tract, particularly gastric carcinoma, but may be associated with a variety of adenocarcinomas, including lung, breast, ovarian, and even hematologic cancers. The pathogenesis of these lesions is uncertain.

The paraneoplastic syndromes may be the earliest indication that a person has cancer and should be regarded as such. They may also represent significant clinical problems, may be potentially lethal in people with cancer, and may mimic metastatic disease and confound treatment. Diagnostic methods focus on both identifying the cause of the disorder and on locating the malignancy responsible. The treatment of paraneoplastic syndromes involves concurrent treatment of the underlying cancer and suppression of the mediator causing the syndrome.

**IN SUMMARY**

There probably is no single body function left unaffected by the presence of cancer. Because tumor cells replace normally functioning parenchymal tissue, the initial manifestations of cancer usually reflect the primary site of involvement. Cancer compresses blood vessels, obstructs lymph flow, disrupts tissue integrity, invades serous cavities, and compresses visceral organs. It may result in development of effusion (i.e., fluid) in the pleural, pericardial, or peritoneal spaces and generalized manifestations such as anorexia and cachexia, fatigue and sleep disorders, and anemia. It may also produce paraneoplastic syndromes that arise from the ability of neoplasms to secrete hormones and other chemical mediators to produce endocrine, hematopoietic, neurologic, and dermatologic syndromes. Many of these manifestations are compounded by the side effects of methods used to treat the disease.

**SCREENING, DIAGNOSIS, AND TREATMENT**

After completing this section of the chapter, you should be able to meet the following objectives:

- Explain the mechanism by which radiation exerts its beneficial effects in the treatment of cancer.
- Differentiate between the action of direct DNA-interacting and indirect DNA-interacting chemotherapeutic agents and cell cycle–specific and cell cycle–independent drugs.
- Describe the three mechanisms whereby biotherapy exerts its effects.

**Screening**

Screening represents a secondary prevention measure for the early recognition of cancer in an otherwise asymptomatic population. Screening can be achieved through observation (e.g., skin, mouth, external genitalia), palpation (e.g., breast, thyroid, rectum and anus, prostate, lymph nodes), and laboratory tests and procedures (e.g., Papanicolaou [Pap] smear, colonoscopy, mammography). It requires a test that will specifically detect early cancers or premalignancies, is cost-effective, and results in improved therapeutic outcomes. For most cancers, stage at presentation is related to curability, with the highest rates reported when the tumor is small and there is no evidence of metastasis. For some tumors, however, metastasis tends to occur early, even from a small primary tumor. For other cancers, such as cancer of the pancreas, no screening methods are currently available. More sensitive screening methods such as tumor markers are being developed for these forms of cancer. Lung cancer is the leading cause of cancer death; however, there are no standard screening guidelines. Physicians and other providers need to determine if it is cost-effective for specific people with certain risk factors to have periodic chest x-rays and CAT scans.

Cancers for which current screening or early detection has led to improvement in outcomes include cancers of the breast (mammography), cervix (Pap smear), colon and rectum (rectal examination, fecal occult blood test, and colonoscopy), prostate (prostate-specific antigen [PSA] testing and transrectal ultrasonography), and malignant melanoma (self-examination). Although not as clearly defined, it is recommended that screening for other types of cancers such as
cancers of the thyroid, testicles, ovaries, lymph nodes, and oral cavity be done at the time of periodic health examinations.

**Diagnostic Methods**

The methods used in the diagnosis and staging of cancer are determined largely by the location and type of cancer suspected. A number of procedures are used in the diagnosis of cancer, including blood tests for tumor markers, cytologic studies and tissue biopsy, endoscopic examinations, ultrasonography, x-ray studies, MRI, computed tomography (CT), and positron emission tomography (PET).

**Tumor Markers**

Tumor markers are antigens expressed on the surface of tumor cells or substances released from normal cells in response to the presence of tumor. Some substances, such as hormones and enzymes, that are produced normally by the involved tissue become overexpressed as a result of cancer. Other tumor markers, such as oncofetal proteins, are produced during fetal development and are induced to reappear later in life as a result of benign and malignant neoplasms. Tumor markers are used for screening, establishing prognosis, monitoring treatment, and detecting recurrent disease. Table 8.5 identifies some of the more commonly used tumor markers and summarizes their source and the cancers associated with them.

The serum markers that have proved most useful in clinical practice are human chorionic gonadotropin (hCG), CA-125, PSA, α-fetoprotein (AFP), carcinoembryonic antigen (CEA), and CD blood cell antigens. A hormone normally produced by the placenta, hCG, is used as a marker for diagnosing, prescribing treatment, and following the disease course in people with high-risk gestational trophoblastic tumors. PSA is used as a marker in prostate cancer, and CA-125 is used as a marker in ovarian cancer. Markers for leukemia and lymphomas are grouped by so-called cluster of differentiation (CD) antigens. The CD antigens help to distinguish among T and B lymphocytes, monocytes, granulocytes, and NK cells, and immature variants of these cells.

Some cancers express fetal antigens that are normally present only during embryonal development. The two that have proved most useful as tumor markers are AFP and CEA. AFP cancers of the thyroid, testicles, ovaries, lymph nodes, and oral cavity be done at the time of periodic health examinations.

</table>
is synthesized by the fetal liver, yolk sac, and gastrointestinal tract and is the major serum protein in the fetus. Elevated levels are encountered in people with primary liver cancers and have also been observed in some testicular, ovarian, pancreatic, and stomach cancers. CEA normally is produced by embryonic tissue in the gut, pancreas, and liver and is elaborated by a number of different cancers. Depending on the serum level adopted for significant elevation, CEA is elevated in approximately 60% to 90% of colorectal carcinomas, 50% to 80% of pancreatic cancers, and 25% to 50% of gastric and breast tumors. As with most other tumor markers, elevated levels of CEA and AFP are found in other, noncancerous conditions, and elevated levels of both depend on tumor size, so that neither is useful as an early screening test for cancer.

As diagnostic tools, tumor markers have limitations. Nearly all markers can be elevated in benign conditions, and most are not elevated in the early stages of malignancy. Hence, tumor markers have limited value as screening tests. Furthermore, they are not in themselves specific enough to permit a diagnosis of a malignancy, but once a malignancy has been diagnosed and shown to be associated with elevated levels of a tumor marker, the marker can be used to assess response to therapy. Examples of tumor markers that assist in evaluating people’s response to therapy, and if a recurrence of breast cancer may be occurring, are CA 15-3 and CA 27-29, both antigens that are found in breast tissue. Extremely elevated levels of a tumor marker can indicate a poor prognosis or the need for more aggressive treatment. Perhaps the greatest value of tumor markers is in monitoring therapy in people with widespread cancer. The level of most cancer markers tends to decrease with successful treatment and increase with recurrence or spread of the tumor.

Cytologic and Histologic Methods

Histologic and cytologic studies are laboratory methods used to examine tissues and cells. Several sampling approaches are available, including cytologic smears, tissue biopsies, and needle aspiration.

Papanicolaou Test. The Pap test is a cytologic method used for detecting cancer cells. It consists of a microscopic examination of a properly prepared slide by a cytotechnologist or pathologist for the purpose of detecting the presence of abnormal cells. The usefulness of the Pap test relies on the fact that the cancer cells lack the cohesive properties and intercellular junctions that are characteristic of normal tissue. Without these characteristics, cancer cells tend to exfoliate and become mixed with secretions surrounding the tumor growth. Although the Pap test is widely used as a screening test for cervical cancer, it can be performed on other body secretions, including nipple drainage, anal washings, pleural or peritoneal fluid, and gastric washings.

Tissue Biopsy. Tissue biopsy, which is of critical importance in diagnosing the correct cancer and histology, involves the removal of a tissue specimen for microscopic study. Biopsies are obtained in a number of ways, including needle biopsy; endoscopic methods, such as bronchoscopy or cystoscopy, which involve the passage of an endoscope through an orifice and into the involved structure; or laparoscopic methods. In some instances, a surgical incision is made from which biopsy specimens are obtained. Excisional biopsies are those in which the entire tumor is removed. The tumors usually are small, solid, palpable masses. If the tumor is too large to be completely removed, a wedge of tissue from the mass can be excised for examination. Appropriate preservation of the specimen includes prompt immersion in a fixative solution such as formalin, with preservation of a portion of the specimen in a special fixative for electron microscopy, or prompt refrigeration to permit optimal hormone, receptor, and other types of molecular analysis. A quick frozen section may be done to determine the nature of a mass lesion or evaluate the margins of an excised tumor to ascertain that the entire neoplasm has been removed.

Fine-needle aspiration is another approach that is widely used. The procedure involves aspirating cells and attendant fluid with a small-bore needle. The method is most commonly used for assessment of readily palpable lesions in sites such as the thyroid, breast, and lymph nodes. Modern imaging techniques have also enabled the method to be extended to deeper structures such as the pelvic lymph nodes and pancreas.

Immunohistochemistry. Immunohistochemistry involves the use of antibodies to facilitate the identification of cell products or surface markers. For example, certain anaplastic carcinomas, malignant lymphomas, melanomas, and sarcomas look very similar under the microscope, but must be accurately identified because their treatment and prognosis are quite different. Antibodies against intermediate filaments have proved useful in such cases because tumor cells often contain intermediate filaments characteristic of their tissue of origin. Immunohistochemistry can also be used to determine the site of origin of metastatic tumors. Many people with cancer present with metastasis. In cases in which the origin of the metastasis is obscure, immunochemical detection of tissue-specific or organ-specific antigens can often help to identify the tumor source. Immunohistochemistry can also be used to detect molecules that have prognostic or therapeutic significance. For example, detection of estrogen receptors on breast cancer cells is of prognostic and therapeutic significance because these tumors respond to antiestrogen therapy.

Microarray Technology. Microarray technology uses “gene chips” that can simultaneously perform miniature assays to detect and quantify the expression of large numbers of genes. The advantage of microarray technology is the ability to analyze a large number of changes in cancer cells to determine overall patterns of behavior that could not be assessed by conventional means. DNA arrays are now commercially available to assist in making clinical decisions regarding breast cancer treatment. In addition to identifying tumor types, microarrays have been used for predicting prognosis and response to therapy, examining tumor changes after therapy, and classifying hereditary tumors.
Staging and Grading of Tumors

The two basic methods for classifying cancers are grading according to the histologic or cellular characteristics of the tumor and staging according to the clinical spread of the disease. Both methods are used to determine the course of the disease and aid in selecting an appropriate treatment or management plan. Grading of tumors involves the microscopic examination of cancer cells to determine their level of differentiation and the number of mitoses. Cancers are classified as grades I, II, III, and IV with increasing anaplasia or lack of differentiation. Staging of cancers uses methods to determine the extent and spread of the disease. Surgery may be used to determine tumor size and lymph node involvement.

The clinical staging of cancer is intended to group people according to the extent of their disease. It is useful in determining the choice of treatment for individual people, estimating prognosis, and comparing the results of different treatment regimens. The TNM system of the American Joint Committee on Cancer (AJCC) is used by most cancer facilities. This system, which is briefly described in Chart 8.2, classifies the disease into stages using three tumor components:

- **T** stands for the size and local spread of the primary tumor.
- **N** refers to the involvement of the regional lymph nodes.
- **M** describes the extent of the metastatic involvement.

The time of staging is indicated as clinical–diagnostic staging (cTNM), postsurgical resection–pathologic staging (pTNM), surgical–evaluative staging (sTNM), retreatment staging (rTNM), and autopsy staging (aTNM).

### Cancer Treatment

The goals of cancer treatment methods fall into three categories: curative, control, and palliative. The most common modalities are surgery, radiation therapy, chemotherapy, and hormonal therapy, and biotherapy. The treatment of cancer involves the use of a carefully planned program that combines the benefits of multiple treatment modalities and the expertise of an interdisciplinary team of specialists, including medical, surgical, and radiation oncologists; clinical nurse specialists; nurse practitioners; pharmacists; and a variety of ancillary personnel.

**Surgery**

Surgery is the oldest treatment for cancer and, until recently, the only treatment that could cure people with cancer. Surgery is now used for diagnosis, staging of cancer, tumor removal, and palliation (i.e., relief of symptoms) when a cure cannot be achieved. The type of surgery to be used is determined by the extent of the disease, the location and structures involved, the tumor growth rate and invasiveness, the surgical risk to the patient, and the quality of life the patient will experience after the surgery. Surgery often is the first treatment used with solid tumors. If the tumor is small and has well-defined margins, the entire tumor often can be removed. If, however, the tumor is large or involves vital tissues, surgical removal may be difficult, if not impossible.

Surgery provides several approaches for cancer treatment. For example, it can be the primary, curative treatment for cancers that are locally or regionally contained, have not metastasized, or have not invaded major organs. It also is used as a component of adjuvant therapy in combination with chemotherapy or radiation therapy in other types of cancers. Surgical techniques also may be used to control oncologic emergencies such as gastrointestinal hemorrhages. Another approach includes using surgical techniques for cancer prophylaxis in families that have a high genetically confirmed risk for developing cancer. For instance, a total colectomy with a colostomy may be suggested for a person with familial adenomatous polyposis coli because of the increased risk for developing cancer by 40 years of age.

Surgical techniques have expanded to include cryosurgery, chemosurgery, laser surgery, and laparoscopic surgery. Cryosurgery involves the instillation of liquid nitrogen into the tumor through a probe. It is used in treating cancers of the liver and prostate. Chemosurgery is used in skin cancers. It involves the use of a corrosive paste in combination with multiple frozen sections to ensure complete removal of the tumor. Laser surgery uses a laser beam to resect a tumor. It has been used effectively in retinal and vocal cord surgery. Laparoscopic surgery involves the performance of abdominal surgery through two small incisions—one for viewing within the cavity and the other for insertion of the instruments to perform the surgery.

Cooperative efforts among cancer centers throughout the world have helped to standardize and improve surgical procedures, determine which cancers benefit from surgical intervention, and establish in what order surgical and other treatment modalities should be used. Increased emphasis also has been placed on the development of surgical techniques that preserve body image and form without compromising essential function. Nerve- and tissue-sparing surgeries are

the primary method used if at all possible even if complete removal of the tumor is the goal.

**Radiation Therapy**

Radiation therapy is one of the most commonly used methods of cancer treatment. It can be used alone as a primary method of therapy or as an adjuvant treatment with surgery, chemotherapy, or both. It can also be used as a palliative treatment to reduce symptoms such as bone pain resulting from metastasis in people with advanced cancers. Radiation is used to treat oncologic emergencies such as superior vena cava syndrome, spinal cord compression, or bronchial obstruction.

Radiation therapy uses high-energy particles or waves to destroy or damage cancer cells. The absorption of energy from radiation in tissue leads to the ionization of molecules or creation of free radicals. Radiation can also produce effects indirectly by interacting with water (which makes up approximately 80% of a cell’s volume) to produce free radicals, which damage cell structures. Radiation can interrupt the cell cycle process, kill cells, or damage DNA in the cells. Radiation must produce double-stranded breaks in DNA to kill a cell, owing to the high capacity of cells for repairing single-stranded breaks.

The therapeutic effects of radiation therapy derive from the fact that the rapidly proliferating and poorly differentiated cells of a cancerous tumor are more likely to be injured than are the more slowly proliferating cells of normal tissue. To some extent, however, radiation is injurious to all rapidly proliferating cells, including those of the bone marrow and the mucosal lining of the gastrointestinal tract. Normal tissue usually is able to recover from radiation damage more readily than cancerous tissue. In addition to its lethal effects, radiation also produces sublethal injury. Recovery from sublethal doses of radiation occurs in the interval between the first dose of radiation and subsequent doses. This is why large total doses of radiation can be tolerated when they are divided into multiple, smaller fractionated doses.

The radiation dose that is chosen for treatment of a particular cancer is determined by factors such as the radiosensitivity of the tumor type, the size of the tumor, and, more important, the tolerance of the surrounding tissues. The term radiosensitivity describes the inherent properties of a tumor that determine its responsiveness to radiation. It varies widely among the different types of cancers and is thought to vary as a function of their position in the cell cycle. Fast-growing cancers have cells that typically are more radiosensitive than slow-growing cancers. The combination of selected cytotoxic drugs with radiation has demonstrated a radiosensitizing effect on tumor cells by altering the cell cycle distribution, increasing DNA damage, and decreasing DNA repair. Radio sensitzers include 5-fluorouracil, capecitabine, paclitaxel, gemcitabine, and cisplatin.

Radiation responsiveness describes the manner in which a radiosensitive tumor responds to irradiation. One of the major determinants of radiation responsiveness is tumor oxygenation because oxygen is a rich source of free radicals that form and destroy essential cell components during irradiation. Many rapidly growing tumors outgrow their blood supply and become deprived of oxygen. The hypoxic cells of these tumors are more resistant to radiation than normal or well-oxygenated tumor cells. Methods of ensuring adequate oxygen delivery, such as adequate hemoglobin levels, are important.

Dose–response curves, which express the extent of lethal tissue injury in relation to the dose of radiation, are determined by the number of cells that survive graded, fractional doses of radiation. The use of more frequent fractionated doses increases the likelihood that the cancer cells will be dividing and in the vulnerable period of the cell cycle during radiation administration. This type of dose also allows time for normal tissues to repair the radiation damage. An important focus of research has been the search for drugs to reduce the biologic effects of radiation on normal tissue. These drugs, known as radioprotectants, would preferentially protect normal cells from the cytotoxic effects of radiation. One drug, amifostine, was considered as possibly decreasing the effect of radiation and impacting survival, but this was found to be incorrect in a study of people with pelvic, lung, and head and neck cancer. Therefore, although there has been some promising developments, more research is necessary regarding radioprotectants.

**Administration.** Therapeutic radiation can be delivered in one of three ways: external beam or teletherapy, with beams generated at a distance and aimed at the tumor in a person; brachytherapy, in which a sealed radioactive source is placed close to or directly in the tumor site; and systemic therapy, when radioisotopes are given orally or injected into the tumor site. Radiation from any source decreases in intensity as a function of the square of the distance from the source. Teletherapy, which is the most commonly used form of radiation therapy, maintains intensity over a large volume of tissue by increasing the source to surface distance. In brachytherapy, the source to surface distance is small; therefore, the effective treatment volume is small.

**External-beam radiation** is most frequently used with a linear accelerator or a cobalt-60 machine. The linear accelerator is the preferred machine because of its versatility and precision of dose distribution, as well as the speed with which treatment can be given. Linear accelerators produce ionizing radiation through a process in which electrons are accelerated at a very high rate, strike a target, and produce high-energy x-rays (photons). The linear accelerator can vary the level of radiation energy that is delivered so that different depths can be treated. Various beam-modifying approaches are used to define and shape the beam, thereby increasing the radiation damage to the tumor site while sparing the normal surrounding tissues. The person is fitted with a plastic mold or cast to keep the body still, while radiation beams are delivered to the body from several directions. Intensity-modulated radiation therapy (IMRT) and three-dimensional conformal radiation therapy (3-D CRT) are advanced forms of external radiation therapy. As with 3-D CRT, computer imaging techniques are used to calculate the most efficient dosages and combinations of radiation...
treatment. This precise mapping of the tumor allows for the delivery of radiation beams that conform to the contours of the tumor, reducing the dose and therefore the toxicity to adjacent normal tissue. Because of its precision, it is even more important that the person remain in the right place and perfectly still during the treatment. This usually requires fabricating a special cast or mold before treatment to keep the body in place.

**Brachytherapy** involves the insertion of sealed radioactive sources into a body cavity (intracavitary) or directly into body tissues (interstitial). Brachytherapy means “short therapy,” implying that the radiation effect is limited to areas close to the radiation source.56 Brachytherapy can be subdivided into high-dose radiation (HDR) and low-dose radiation (LDR) according to the rate at which the radiation is delivered. HDR uses a single highly radioactive source that is attached to a cable and housed in a robotic machine referred to as an HDR remote afterloader. When the treatment is delivered, the radiation source is pushed from the remote afterloader through a tube to a location near the tumor site. Remote afterloading machines make it possible to insert a radioactive material (e.g., cesium-137, iridium-192) into a tumor area for a specific time and remove it while oncology personnel are outside the treatment room. This minimizes staff radiation exposure and decreases treatment times by allowing use of intermediate- and high-dose radioactive sources.56 In contrast, the radiation source for LDR brachytherapy may be packed into catheter devices or sealed radiation sources (e.g., beads, seeds) and placed directly in or near the area being treated. LDR therapy can be temporary or permanent. Temporary LDR brachytherapy can be accomplished as an inpatient procedure, with radiation applicators and sources remaining in the person for a few days. Radioactive materials with a relatively short half-life, such as iodine-125 or palladium-103, are commonly encapsulated and used in permanent implants (e.g., seed implants used to treat prostate cancer).

**Unsealed internal radiation sources** are injected intravenously or administered by mouth. Iodine-131, which is given by mouth, is used in the treatment of thyroid cancer. Stereotactic radiosurgery is a method of destroying brain tumors and brain metastases by delivering a single large dose of radiation through stereotactically directed narrow beams. Gamma knife radiosurgery allows the application of focused radiation for limited brain metastasis and is associated with fewer long-term complications, such as cognitive dysfunction, compared to whole-brain radiation.

**Adverse Effects.** Unfortunately radiation therapy negatively affects normal tissue that is rapidly proliferative similar to malignant cells. During radiation treatment, injury to normal cells can produce adverse effects. Tissues within the treatment fields that are most frequently affected are the skin, the mucosal lining of the gastrointestinal tract, and the bone marrow. Anorexia, nausea, emesis, and diarrhea are common with abdominal and pelvic irradiation. These symptoms are usually controlled by medication and dietary measures. The primary systemic effect is fatigue. Most of these side effects are temporary and reversible.

Radiation can also cause bone marrow suppression, particularly when it is delivered to the bone marrow in skeletal sites. Subsequently, the complete blood count is affected, resulting in an initial decrease in the number of the leukocytes, followed by a decrease in thrombocytes (platelets) and, finally, red blood cells. This predisposes the person to infection, bleeding, and anemia, respectively. Frequent blood counts are used during radiation therapy to monitor bone marrow function.

External-beam radiation must first penetrate the skin and, depending on the total dose and type of radiation used, skin reactions may develop. With moderate doses of radiation, the hair falls out spontaneously or when being combed after the 10th to the 14th day. With larger doses, erythema develops (much like sunburn) and may turn brown, and at higher doses, patches of dry or moist desquamation may develop. Fortunately, reepithelialization takes place after the treatments have been stopped. Mucositis or desquamation of the oral and pharyngeal mucous membranes, which sometimes may be severe, may occur as a predictable side effect in people receiving head and neck irradiation. Pain and difficulty eating and drinking can negatively affect the person’s nutritional status. Pelvic radiation can cause impotence or erectile dysfunction in men and vaginal irritation, dryness, and discharge, dyspareunia, and, as a late effect, vaginal stenosis in women.

**Chemotherapy**

Cancer chemotherapy has evolved as one of the major systemic treatment modalities for cancer. Unlike surgery and radiation, chemotherapy is a systemic treatment that enables drugs to reach the site of the tumor as well as other distant sites. Chemotherapeutic drugs may be the primary form of treatment, or they may be used as part of a multimodal treatment plan. It is the primary treatment for most hematologic and some solid tumors, including choriocarcinoma, testicular cancer, acute and chronic leukemia, non-Hodgkin and Hodgkin lymphomas, and multiple myeloma. In people with widespread disseminated disease, chemotherapy provides only palliative rather than curative therapy at present.

Cancer chemotherapeutic drugs exert their effects through several mechanisms. At the cellular level, they exert their lethal action by targeting processes that prevent cell growth and replication. Chemotherapy kills cancer cells by stopping DNA, RNA, and protein synthesis; influencing enzyme production; and generally preventing cell mitosis.2 Under ideal conditions, anticancer drugs would eradicate cancer cells without damaging normal tissues. Although in the process of development, targeted cancer agents are not available without toxic effects.

For most chemotherapy drugs, the relationship between tumor cell survival and drug dose is exponential, with the number of cells surviving being proportional to the drug dose and the number of cells at risk for exposure being proportional to the destructive action of the drug. Chemotherapeutic drugs are most effective in treating tumors that have a high growth fraction because of their ability to kill rapidly dividing cells.
A major problem in cancer chemotherapy is the development of cellular resistance. Experimentally, drug resistance can be highly specific to a single agent and is usually based on genetic changes in a given tumor cell. In other instances, a multidrug-resistant phenomenon encompassing anticancer drugs with differing structures occurs. This type of resistance often involves the increased expression of transmembrane transporter genes involved in drug efflux.

Chemotherapy drugs are commonly classified according to their site and mechanism of action. Chemotherapy drugs that have similar structures and effects on cell function usually are grouped together, and these drugs usually have similar side effect profiles. Direct DNA-interacting and indirect DNA-interacting agents are two major categories of chemotherapy drugs. Other systemic agents include hormonal and molecularly targeted agents. Cancer chemotherapy drugs may also be classified as either cell cycle specific or cell cycle nonspecific. Drugs are cell cycle specific if they exert their action during a specific phase of the cell cycle. For example, methotrexate, an antimitabolite, acts by interfering with DNA synthesis and thereby interrupts the S phase of the cell cycle. Drugs that are cell cycle nonspecific exert their effects throughout all phases of the cell cycle. The alkylating agents are cell cycle nonspecific and act by disrupting DNA when the cells are in the resting state as well as when they are dividing. Because chemotherapy drugs differ in their mechanisms of action, cell cycle–specific and cell cycle–nonspecific agents are often combined to treat cancer.

**Direct DNA-Interacting Agents.** The direct DNA-interacting agents include the alkylating agents, antitumor antibiotics, and topoisomerase inhibitors. As a class, the alkylating agents exert their cytotoxic effects by transferring their alkyl group to many cellular constituents. Alkylation of DNA within the cell nucleus is probably the major interaction that causes cell death. Alkylating agents have direct vesicant effects and can damage tissues at the site of injection as well as produce systemic toxicity. Toxicities are generally dose related and occur particularly in rapidly proliferating tissues such as bone marrow, the gastrointestinal tract, and reproductive tissues.

The **antitumor antibiotics** are substances produced by bacteria that in nature appear to provide protection against hostile microorganisms. As a class they bind directly to DNA and frequently undergo electron transfer reactions to generate free radicals in close proximity to DNA, resulting in DNA damage in the form of single breaks or cross-links. All of the anticancer antibiotics in clinical use are originally isolated by the soil microbe, *Streptomyces*. These include the anthracyclines, dactinomycin, bleomycin, and mitomycin. The anthracycline antibiotics (e.g., doxorubicin and daunorubicin) are among the most widely used cytotoxic cancer drugs. The main dose-limiting toxicity of all anthracyclines is cardiotoxicity and myelosuppression, with neutropenia more commonly observed than thrombocytopenia. Two forms of cardiotoxicity can occur—acute and chronic. The acute form occurs within the first 2 to 3 days of therapy and presents with arrhythmias, conduction disorders, other electrocardiographic changes, pericarditis, and myocarditis. This form is usually transient and in most cases asymptomatic. The chronic form of cardiotoxicity results in a dose-dependent dilated cardiomyopathy. Efforts to minimize the toxicity profile of the antitumor antibiotics have resulted in the development of analog compounds (e.g., idarubicin, epirubicin). Liposome technology has been used with two antitumor antibiotics (*i.e.*, doxorubicin and daunorubicin) to develop chemotherapy drugs that are encapsulated by coated liposomes.

The DNA **topoisomerase inhibitors** block cell division by interfering with the action of the topoisomerase enzymes that break and rejoin phosphodiester bonds in the DNA strands to prevent them from tangling during separation and unwinding of the double helix. Topoisomerase I produces single-strand breaks (nicks) and topoisomerase II double-strand breaks. The epipodophyllotoxins (etoposide and teniposide) are topoisomerase II inhibitors that block cell division in the late S to G2 phase of the cell cycle. The camptothecins (topotecan, irinotecan) inhibit the action of topoisomerase I, the enzyme responsible for cutting and rejoining single DNA strands. Inhibition of this enzyme interferes with rescaling of the breaks and DNA damage.

**Indirect DNA-Interacting Agents.** The indirect DNA-interacting agents include the antimitobolites and mitotic spindle inhibitors. The antimetabolites (folic acid antagonists and purine and pyrimidine antagonists) interrupt the biochemical pathways relating to nucleotide and nucleic acid synthesis. Antimetabolites can cause DNA damage indirectly through misincorporation into DNA, abnormal timing of DNA synthesis, or by causing abnormal functioning of purine and pyrimidine biosynthetic enzymes. They tend to convey their greatest effect during the S phase of the cell cycle. Because of their S-phase specificity, the antimetabolites have been shown to be more effective when given as a prolonged infusion. Common side effects include stomatitis, diarrhea, and myelosuppression.

The plant alkaloids, including the vinca alkaloids and taxanes, are drugs affecting the microtubule structures required for formation of the cytoskeleton and mitotic spindle. Although each group of drugs affects the microtubule, their mechanism of action differs. The vinca alkaloids (*e.g.*, vinblastine, vincristine) inhibit tubulin polymerization, which disrupts assembly of microtubules. This inhibitory effect results in mitotic arrest in metaphase, bringing cell division to a stop, which then leads to cell death. Vinblastine is a potent vesicant and care must be taken in its administration. Toxicities include nausea and vomiting, bone marrow suppression, and alopecia. Despite similarities in their mechanisms of action, vincristine has a different spectrum of actions and toxicities than vinblastine. The main dose-limiting toxicity is neurotoxicity, usually expressed as a peripheral sensory neuropathy, although autonomic nervous system dysfunction (*e.g.*, orthostatic hypotension, sphincter problems, paralytic ileus), cranial nerve palsy, ataxia, seizures, and coma have
been observed. The taxanes (e.g., paclitaxel, docetaxel) differ from the vinca alkaloids in that they stabilize the microtubules against depolymerization. The stabilized microtubules are unable to undergo the normal changes necessary for cell cycle completion. These drugs are administered intravenously and require the use of a vehicle that can cause hypersensitivity reactions. In addition to hypersensitivity reactions, their side effect profile includes myelosuppression and peripheral neuropathy in the form of glove-and-sock numbness and paresthesia.

Combination Chemotherapy. Combination chemotherapy has been found to be more effective than treatment with a single drug. Combination chemotherapy creates a more hostile environment for tumor cell growth through higher drug concentrations and prevents the development of resistant clones of cancer cells. With this method, several drugs with different mechanisms of action, metabolic pathways, times of onset of action and recovery, side effects, and times of onset of side effects are used. Drugs used in combination must be individually effective against the tumor and may be synergistic with each other. Routes of administration and dosage schedules are carefully designed to ensure optimal delivery of the active forms of the drugs to a tumor during the sensitive phase of the cell cycle.

Administration. Many of the cancer chemotherapy drugs are administered intravenously. Venous access devices (VADs) often are used for people with poor venous access and those who require frequent or continuous intravenous therapy. The VAD can be used for home administration of chemotherapy drugs, blood sampling, and administration of blood components. These systems access the venous circulation either through an externalized catheter or an implanted catheter with access ports. In some cases, the drugs are administered by continuous infusion using an ambulatory infusion pump that allows the person to remain at home and maintain his or her activities.

Adverse Effects. Chemotherapy is administered on a dose–response basis (i.e., the more drug administered, the greater the number of cancer cells killed). Chemotherapeutic drugs affect neoplastic cells and the rapidly proliferating cells of normal tissue. The nadir (i.e., lowest point) is the point of maximal toxicity for a given adverse effect of a drug and is stated in the time it takes to reach that point. Because many toxic effects of chemotherapeutic drugs persist for some time after the drug is discontinued, the nadir times and recovery rates are useful guides in evaluating the effects of cancer therapy. Some side effects appear immediately or after a few days (acute), some within a few weeks (intermediate), and others months to years after chemotherapy administration (long term).

Most chemotherapeutic drugs cause pancytopenia due to bone marrow suppression, resulting in neutropenia (causing infections), anemia (resulting in fatigue), and thrombocytopenia (increasing risk for bleeding). The availability of hematopoietic growth factors (e.g., granulocyte colony-stimulating factor [G-CSF] and IL-11, a cytokine, which stimulates platelet production) has shortened the period of myelosuppression, thereby reducing the need for hospitalizations due to infection and bleeding. The growth factor epoetin alfa, a form of the protein erythropoietin manufactured by the kidneys to help produce red blood cells is used with a select population of people. The drug has been under scrutiny since 2004 when it was found that it could promote tumor progression and shorten survival. The risk–benefit of epoetin needs to be weighed carefully before the drug is given for chemotherapy-induced anemia.

Anorexia, nausea, and vomiting are common problems associated with cancer chemotherapy. The severity of the vomiting is related to the emetic potential of the particular drug. These symptoms can occur within minutes or hours of drug administration and are thought to be due to stimulation of the chemoreceptor trigger zone in the medulla that initiates vomiting. The chemoreceptor trigger zone responds to levels of chemicals circulating in the blood. The acute symptoms usually subside within 24 to 48 hours and often can be relieved by antiemetics. The pharmacologic approaches to prevent chemotherapy-induced nausea and vomiting have greatly improved over the past several decades. Serotonin receptor (5-HT) antagonists (e.g., ondansetron, granisetron, dolasetron, palonosetron) facilitate the use of highly emetic chemotherapy drugs by more effectively reducing the nausea and vomiting induced by these drugs. These antiemetics are effective when given by both the oral and intravenous routes.

Alopecia or hair loss results from impaired proliferation of the hair follicles and is a side effect of a number of cancer drugs. It usually is temporary, and the hair tends to regrow when treatment is stopped. The rapidly proliferating structures of the reproductive system are particularly sensitive to the action of cancer drugs. Women may experience changes in menstrual flow or have amenorrhea. Men may have a decreased sperm count (i.e., oligospermia) or absence of sperm (i.e., azoospermia). Teratogenic or mutagenic effects can also occur from taking chemotherapy.

Chemotherapy drugs are toxic to all cells. The mutagenic, carcinogenic, and teratogenic potential of these drugs has been strongly supported by both animal and human studies. Because of these potential risks, special care is required when handling or administering the drugs. Drugs, drug containers, and administration equipment require special disposal as hazardous waste. The Occupational Safety and Health Administration (OSHA), the Oncology Nursing Society (ONS), and the American Society of Hospital Pharmacists (ASHP) have created chemotherapy guidelines dedicated to their safe administration.

Epidemiologic studies have shown an increased risk for second malignancies such as acute leukemia after long-term use of alkylating agents. These second malignancies are thought to result from direct cellular changes produced by the drug or from suppression of the immune response.
Hormonal Therapy

Hormonal therapy consists of administration of drugs designed to disrupt the hormonal environment of cancer cells. The actions of hormones and anti-hormones depend on the presence of specific receptors in the tumor. Among the tumors that are known to be responsive to hormonal manipulation are those of the breast, prostate, and endometrium. Additionally, other cancers, such as Kaposi sarcoma and renal, liver, ovarian, and pancreatic cancer, can be treated with hormonal therapy. The theory behind the majority of hormone-based cancer treatments is to deprive the cancer cells of the hormonal signals that otherwise would stimulate them to divide.

The therapeutic options for altering the hormonal environment in the woman with breast cancer or the man with prostate cancer include surgical and pharmacologic measures. Surgery involves the removal of the organ responsible for the hormone production that is stimulating the target tissue (e.g., oophorectomy in women or orchietomy in men). Pharmacologic methods focus largely on reducing circulating hormone levels or changing the hormone receptors so that they no longer respond to the hormone.

Pharmacologic suppression of circulating hormone levels can be effected through pituitary desensitization, as with the administration of androgens, or through the administration of gonadotropin-releasing hormone (GnRH) analogs that act at the level of the hypothalamus to inhibit gonadotropin production and release. Another class of drugs, the aromatase inhibitors, is used to treat some forms of early-stage breast cancer. These drugs act by interrupting the biochemical processes that convert the adrenal androgen androstenedione to estrone. Aromatization of an androgenic precursor into an estrogen occurs in body fat. Because estrogen promotes the growth of breast cancer, estrogen synthesis in adipose tissue can be an important factor in breast cancer growth in postmenopausal women.

Hormone receptor function can be altered by the administration of pharmacologic doses of exogenous hormones that act by producing a decrease in hormone receptors, or by anti-hormone drugs (i.e., anti-estrogens [tamoxifen, fulvestrant] and anti-androgens [flutamide, bicalutamide, nilutamide]) that bind to hormone receptors, making them inaccessible to hormone stimulation. Initially, people often respond favorably to hormonal treatments, but eventually the cancer becomes resistant to hormonal manipulation, and other approaches must be sought to control the disease.

Biotherapy

Biotherapy involves the use of immunotherapy and biologic response modifiers as a means of changing the person’s own immune response to cancer. The major mechanisms by which biotherapy exerts its effects are modifications of host responses or tumor cell biology.

Immunotherapy. Immunotherapy techniques include active and passive, or adoptive, immunotherapy. Active immunotherapy involves nonspecific treatments such as bacille Calmette-Guérin (BCG). BCG is an attenuated strain of the bacterium that causes bovine tuberculosis. It acts as a nonspecific stimulant of the immune system and is instilled into the bladder as a means of treating superficial bladder cancer. Passive or adoptive immunotherapy involves the transfer of cultured immune cells into a tumor-bearing host. Early research efforts with adoptive immunotherapy involved the transfer of sensitized NK cells or T lymphocytes, combined with cytokines, to the tumor-bearing host in an attempt to augment the host’s immune response. However, randomized clinical trials demonstrated no benefit from the addition of the cellular component beyond the benefit from the cytokines alone. Further research has focused on using antigen-presenting dendritic cells as delivery vehicles for tumor antigens.

Biologic Response Modifiers. Biologic response modifiers can be grouped into three types: cytokines, which include the interferons and ILs; monoclonal antibodies (MoAbs); and hematopoietic growth factors. Some agents, such as interferons, have more than one biologic function, including antiviral, immunomodulatory, and antiproliferative actions. The interferons are endogenous polypeptides that are synthesized by a number of cells in response to a variety of cellular or viral stimuli. The three major types of interferons are alpha (α), beta (β), and gamma (γ), each group differing in terms of their cell surface receptors. The interferons appear to inhibit viral replication and also may be involved in inhibiting tumor protein synthesis and in prolonging the cell cycle, increasing the percentage of cells in the G0 phase. Interferons stimulate NK cells and T lymphocyte killer cells. Interferon-γ has been approved for the treatment of hairy cell leukemia, AIDS-related Kaposi sarcoma, and CML and as adjuvant therapy for people at high risk for recurrent melanoma.

The ILs are cytokines that affect communication between cells by binding to receptor sites on the cell surface membranes of the target cells. Of the 18 known ILs, IL-2 has been the most widely studied. A recombinant human IL-2 (rIL-2, aldesleukin) has been approved by the FDA and is being used for the treatment of metastatic renal cell and melanoma.

MoAbs are highly specific antibodies (e.g., IgG, which is the most commonly used immunoglobulin) derived from cloned cells. Scientists have developed methods for producing large quantities of MoAbs that are specific for tumor cells. For a MoAb to be therapeutic as a cancer treatment modality, a specific target antigen should be present on cancer cells only. The MoAbs act by interfering with cell membrane–bound targets by blocking the ligand–receptors, immune modulation, complement-mediated cytotoxicity, and antibody-related cell cytotoxicity.

Targeted Therapy

Targeted cancer therapy uses drugs that selectively attack malignant cells without causing harm to normal cells. It focuses on altered molecules and signaling pathways that allow cancer cells to grow and spread in an uncontrolled manner. The first targeted therapies were the MoAbs.
Other targeted therapies include small molecules that block specific enzymes and growth factors involved in cancer cell growth. The protein tyrosine kinases are intrinsic components of the signaling pathways for growth factors involved in the proliferation of lymphocytes and other cell types. Imatinib mesylate (Gleevec) is a protein tyrosine kinase inhibitor indicated in the treatment of chronic myelogenous leukemia. The epidermal growth factor receptor signaling pathway has long been proposed as a target for an anticancer drug. Angiogenesis is continually being explored for targeted cancer therapy. An antiangiogenic agent, bevacizumab, targets and blocks vascular endothelial growth factor, which is released by many cancers to stimulate proliferation of new blood vessels. It was approved in 2004 for metastatic colon cancer and non–small cell cancer. The combination of bevacizumab and chemotherapy was found to increase objective responses, median time to progression, and survival time of people with metastatic colorectal cancer, compared with chemotherapy alone.

Another class of drugs, the apoptosis-inducing drugs, causes cancer cells to undergo apoptosis by interfering with proteins involved in the process. The FDA approved bortezomib in 2008 as first-line treatment for multiple myeloma. It causes cancer cells to die by blocking enzymes known as proteosomes, which help regulate cell function and growth.

IN SUMMARY

The methods used in the diagnosis of cancer vary with the type of cancer and its location. Because many cancers are curable if diagnosed early, health care practices designed to promote early detection are important. Histologic studies are done in the laboratory using cells or tissue specimens. There are two basic methods of classifying tumors: grading according to the histologic or tissue characteristics and clinical staging according to spread of the disease. The TNM system for clinical staging of cancer takes into account tumor size, lymph node involvement, and presence of metastasis.

Treatment plans that use more than one type of therapy, often in combination, are providing cures for a number of cancers that a few decades ago had a poor prognosis and are increasing the life expectancy in other types of cancer. Surgical procedures are more precise and less invasive, preserving organ function and resulting in better quality-of-life outcomes. Newer radiation equipment and novel radiation techniques permit greater and more controlled destruction of cancer cells while sparing normal tissues. Cancer chemotherapy has evolved as one of the major systemic treatment modalities for cancer. Unlike surgery and radiation, chemotherapy is a systemic treatment that enables drugs to reach the site of the tumor as well as other distant sites. The major classifications of chemotherapy drugs are the direct DNA-interacting (alkylating agents, antitumor antibiotics, and topoisomerase inhibitors) and indirect DNA-interacting agents (antimetabolites and mitotic spindle inhibitors). Cancer chemotherapeutic drugs may also be classified as either cell cycle specific or cell cycle nonspecific depending on whether they exert their action during a specific phase of the cell cycle. Other systemic agents include hormonal and molecularly targeted agents that block specific enzymes and growth factors involved in cancer cell growth.

CANCER IN CHILDHOOD

Cancer in children is relatively rare, accounting for about 1% of all malignancies in the United States. Although rare, cancer remains the second leading cause of death among children 1 to 14 years of age in the United States. In the United States in 2011, 11,210 children were diagnosed with cancer and 1320 children died of cancer. Common cancers that occur in children include leukemia, non-Hodgkin and Hodgkin lymphomas, and bone cancers (osteosarcoma and Ewing sarcoma). The overall survival rate for children is 80%.

Incidence and Types

The spectrum of cancers that affect children differs markedly from those that affect adults. Although most adult cancers are of epithelial cell origin (e.g., lung cancer, breast cancer, colorectal cancers), childhood cancers differ in that they generally involve the hematopoietic system, nervous system, soft tissues, bone, and kidneys.

During the first year of life, embryonal tumors such as Wilms tumor, RB, and neuroblastoma are among the most common types of tumors. Embryonal tumors along with acute leukemia, non-Hodgkin lymphoma, and gliomas have a peak incidence in children 2 to 5 years of age. As children age, especially after they pass puberty, bone malignancies, Hodgkin lymphoma, gonadal germ cell tumors (testicular and ovarian carcinomas), and various carcinomas such as thyroid cancer and malignant melanoma increase in incidence.

Embryonal Tumors

A number of the tumors of infancy and early childhood are embryonal in origin, meaning that they exhibit features of organogenesis similar to that of embryonic development. Because of
Neuroblastoma. Neuroblastomas arise from the primordial neural crest tissue in the sympathetic nervous system and adrenal medulla. It is the second most common solid malignancy in childhood after brain tumors. About 40% of neuroblastomas arise in the adrenal gland, with the remainder occurring anywhere along the sympathetic chain, most commonly in the paravertebral region of the abdomen and posterior medias-tinum. Tumors may arise in numerous other sites, including the pelvis, neck, and within the brain. Clinical manifestations vary with the primary site and neuroendocrine function of the tumor. In children younger than 2 years of age, neuroblastoma generally presents with large abdominal masses, fever, and possibly weight loss. Bone pain suggests metastatic disease. About 90% of the tumors, regardless of location, secrete catecholamines, which is an important diagnostic feature (i.e., elevated blood levels of catecholamines and elevated urine levels of catecholamine metabolites).

Unfortunately, neuroblastoma is also an extremely malignant neoplasm, particularly in children with advanced disease. Although the 5-year survival rate has improved, neuroblastoma continues to account for approximately 15% of all childhood cancer deaths. Infants tend to have a better prognosis than older children. Almost all children with neuroblastoma are diagnosed before 5 years of age, and the younger the child is diagnosed, the more positive the prognosis is.

Biology of Childhood Cancers

As with adult cancers, there probably is no single cause of childhood cancer. Although a number of genetic conditions are associated with childhood cancer, such conditions are relatively rare, suggesting an interaction between genetic susceptibility and environmental exposures. There are some inheritable conditions that increase susceptibility to childhood and even adult cancer. An example is Down syndrome, which actually increases the risk of acute lymphoblastic leukemia (ALL) and acute myelogenous leukemia (AML).

Although constituting only a small percentage of childhood cancers, the biology of a number of these tumors illustrates several important biologic aspects of neoplasms, such as the two-hit theory of recessive tumor suppressor genes (e.g., RB gene mutation in RB); defects in DNA repair; and the histologic similarities between organogenesis and oncogenesis. Syndromes associated with defects in DNA repair include xeroderma pigmentosa, in which there is increased risk of skin cancers owing to defects in repair of DNA damaged by ultraviolet light. The development of childhood cancers has also been linked to genomic imprinting. The inactivation is determined by whether the gene is inherited from the mother or father. For example, the maternal allele for the insulin-like growth factor-2 (IGF-2) gene normally is inactivated (imprinted). In some Wilms tumors, loss of imprinting (re-expression of the maternal allele) can be demonstrated by overexpression of the IGF-2 protein, which is an embryonal growth factor.

Diagnosis and Treatment

Because most childhood cancers are curable, early detection is imperative. In addition, there are several types of cancer for which less therapy is indicated than for more advanced disease. In fact, early detection often minimizes the amount and duration of treatment required for cure and may therefore not only increase the potential for cure but spare the child intensive or prolonged treatment.

Unfortunately, there are no early warning signs or screening tests for cancer in children. Prolonged fever, persistent lymphadenopathy, unexplained weight loss, growing masses (especially in association with weight loss), and abnormalities of CNS function should be viewed as warning signs of cancer in children. Because these signs and symptoms of cancer are often similar to those of common childhood diseases, it is easy to miss a cancer diagnosis in the early stages.

Diagnosis of childhood cancers involves many of the same methods used in adults. Histologic examination is usually an essential part of the diagnostic procedure. Accurate disease staging is especially beneficial in childhood cancers, in which the potential benefits of treatment must be carefully weighed against potential long-term effects.

The treatment of childhood cancers is complex, intensive, prolonged, and continuously evolving. It usually involves appropriate multidisciplinary and multimodal therapies, as well as the evaluation for recurrent disease and late effects of the disease and therapies used in its treatment.

Two modalities are frequently used in the treatment of childhood cancer, with chemotherapy being the most widely used, followed, in order of use, by surgery, radiation therapy, and biologic agent therapy. Chemotherapy is more widely used in treatment of children with cancer than in adults because children better tolerate the acute adverse effects and, in general, pediatric tumors are more responsive to chemotherapy than adult cancers.

With improvement in treatment methods, the number of children who survive childhood cancer continues to increase. As a result of cancer treatment, almost 80% of children and adolescents with a diagnosis of cancer become long-term survivors. Unfortunately, therapy may produce late sequelae, such as impaired growth, neurologic dysfunction, hormonal dysfunction, cardiomyopathy, pulmonary fibrosis, and risk for second malignancies. Thus, one of the growing challenges is providing appropriate health care to survivors of childhood and adolescent cancers.

Radiation Therapy

Radiation therapy poses the risk of long-term effects for survivors of childhood cancer. The late effects of radiation therapy are influenced by the organs and tissues included in the treatment field, type of radiation administered, daily fractional
and cumulative radiation dose, and age at treatment. There is increased risk for melanoma, squamous cell carcinoma, and basal cell carcinoma. Musculoskeletal changes are also common after radiation. Even with current methods, survivors may have changes leading to pain and altered musculoskeletal function.

Cranial radiation therapy (CRT) has been used to treat brain tumors, ALL, head and neck soft tissue tumors, and RB. The most common late effect of moderate- to high-dose whole-brain radiation is diminished intellectual function. Brain tumor survivors treated at a younger age are particularly susceptible. Cranial radiation is also associated with neuro-endocrine disorders, particularly growth hormone deficiency. Thus, children reaching adulthood after CRT may have reduced physical stature. The younger the age and the higher the radiation dose, the greater the deviation from normal growth. Growth hormone deficiency in adults is associated with increased prevalence of dyslipidemia, insulin resistance, and cardiovascular mortality. Moderate doses of CRT are also associated with obesity, particularly in female patients. For many years, whole-brain radiation or CRT was the primary method of preventing CNS relapse in children with ALL. Recognition of cognitive dysfunction associated with CRT has led to the use of other methods of CNS prophylaxis.

Radiation to the chest or mantle field (lymph nodes of neck, subclavicular, axillary, and mediastinal areas) is often used in treatment of Hodgkin and non-Hodgkin lymphomas and metastases to the lung. This field exposes the developing breast tissue, heart, and lungs to ionizing radiation. Female survivors who were treated with this type of radiation face significant risk for development of breast cancer. Much of the heart is exposed in chest and mantle radiation fields, resulting in subsequent premature coronary artery, valvular, and pericardial disease. Exposure of the lungs to radiation therapy can result in a reduction in pulmonary function. Thyroid disease, particularly hypothyroidism, is common after mantle or neck radiation.

Childhood cancer survivors treated with abdominal or pelvic radiation are also at risk for a variety of late health problems involving the gastrointestinal tract, liver, spleen, kidneys, and genitourinary tract structures, including the gonads. Gastrointestinal tract complications include chronic mucosal inflammation that interferes with absorption and digestion of nutrients. Chronic radiation injury to the kidneys may interfere with glomerular or tubular function, and fibrosis from pelvic radiation may adversely affect bladder capacity and function. The adverse effects of radiation on gonadal function vary by age, sex, and cumulative dose. Delayed sexual maturation in boys and girls can result from irradiation of the gonads. In boys, sperm production is reduced in a dose-dependent manner. In girls, radiation to the abdomen, pelvis, and spine is associated with increased risk of ovarian failure, especially if the ovaries are in the treatment field.

Chemotherapy

Chemotherapy also poses the risk of long-term effects for survivors of childhood cancer. Potential late effects of alkylating agents include dose-related gonadal injury (hypogonadism, infertility, and early menopause). Alkylating agent therapy has also been linked to dose-related secondary acute myelogenous leukemia, pulmonary fibrosis, kidney disease, and bladder disorders. Anthracyclines, including doxorubicin and daunomycin, which are widely used in treatment of childhood cancers, can result in cardiomyopathy and eventual congestive heart failure. The late effects of cisplatin and carboplatin, the most frequently used nonclassic alkylators, are nephrotoxicity, ototoxicity, and neurotoxicity. Although combination chemotherapy increases the effectiveness of treatment, it may also be associated with increased risk of side effects if the agents have a similar spectrum of toxicity. Intrathecal combination chemotherapy to prevent relapse of ALL in the CNS, which is a sanctuary for ALL cells, is known to cause significant and persistent cognitive impairment in many children.

IN SUMMARY

Although most adult cancers are of epithelial cell origin, most childhood cancers usually involve the hematopoietic system, nervous system, or connective tissue. Heritable forms of cancer tend to have an earlier age of onset, a higher frequency of multifocal lesions in a single organ, and bilateral involvement of paired organs or multiple primary tumors. The early diagnosis of childhood cancers often is missed because the signs and symptoms mimic those of other childhood diseases. With improvement in treatment methods, the number of children who survive childhood cancer is continuing to increase. As these children approach adulthood, there is continued concern that the lifesaving therapy they received during childhood may produce late effects, such as impaired growth, cognitive dysfunction, hormonal dysfunction, cardiomyopathy, pulmonary fibrosis, and risk for second malignancies.

REVIEW EXERCISES

1. A 30-year-old woman has experienced heavy menstrual bleeding and is told she has a uterine tumor called a leiomyoma. She is worried she has cancer.
   A. What is the difference between a leiomyoma and leiomyosarcoma?
   B. How would you explain the difference to her?
2. Among the characteristics of cancer cells are lack of cell differentiation, impaired cell-to-cell adhesion, and loss of anchorage dependence.
   A. Explain how each of these characteristics contributes to the usefulness of the Pap smear as a screening test for cervical cancer.

Continued
3. A 12-year-old boy is seen at the pediatric cancer clinic with osteosarcoma. His medical history reveals that his father had been successfully treated for RB as an infant.
   A. Relate the genetics of the RB gene and the "two-hit" hypothesis to the development of osteosarcoma in the son of the man who had RB.

4. A 48-year-old man presents at his health care clinic with complaints of leg weakness. He is a heavy smoker and has had a productive cough for years. Subsequent diagnostic tests reveal he has a small cell lung cancer with brain metastasis. His proposed plan of treatment includes chemotherapy and radiation therapy.
   A. What is the probable cause of the leg weakness, and is it related to the lung cancer?
   B. Relate this man's smoking history to the development of lung cancer.
   C. Explain the mechanism of cancer metastasis.
   D. Explain the mechanisms whereby chemotherapy and irradiation are able to destroy cancer cells while having a lesser or no effect on normal cells.

5. A 17-year-old-girl is seen by a guidance counselor at her high school because of problems in keeping up with assignments in her math and science courses. She tells the counselor that she had leukemia when she was 2 years old and was given radiation treatment to the brain. She confides that she has always had more trouble with learning than her classmates and thinks it might be due to the radiation. She also relates that she is shorter than her classmates, and this has been bothering her.
   A. Explain the relationship between CRT and decreased cognitive function and short stature.
   B. What other neuroendocrine problems might this girl have as a result of the radiation treatment?

Chapter 8 Neoplasia

Visit thePoint http://thePoint.lww.com for animations, journal articles, and more!
Mrs. Iona Smith, 38 years old, presents with a malar (butterfly) rash, generalized joint discomfort, fatigue, and intense photosensitivity. She is worked up for systemic lupus erythematosus (SLE). Mrs. Smith states that she has experienced these symptoms intermittently for about 9 months and is under considerable stress. Her extended family (parents, sister, two brothers, and grandmother) were all killed in a motor vehicle accident about 1 year ago when they were traveling to her home for Christmas. She and her husband have a child with Asperger autism, and her husband recently lost his job. Lacking health care insurance, she has put off going to a doctor. Upon questioning, she has no personal or family history of SLE.

The clinic health care provider does some blood work and schedules a return appointment in 3 weeks. The blood work indicates an elevated white blood cell count and lymphocytes count, a decreased platelet count, and hemolytic anemia. Serologic testing identifies three autoantibodies in Mrs. Smith’s blood sample that are strongly indicative of SLE: anti-Smith antibody, lupus anticoagulant, and antinuclear antibody (ANA). She also has significant amounts (+2) of protein in her urine, indicating that she is already experiencing some degree of renal disease. Her symptoms and clinical results lead to the diagnosis of SLE. Iona’s case is discussed in greater detail in Chapter 9 and Chapter 11.
Stress has become an increasingly discussed topic in today’s world. The concept is discussed extensively in the health care fields and is found in economics, political science, business, and education. In the popular press, the physiologic response to stress is often implicated as a contributor to a variety of individual physical and mental challenges and societal problems. Approximately 25% of Americans perceive their stress level as high, which reflects a score of 8 to 10 on a 10-point scale. Fifty percent of Americans perceive their stress levels to be moderate, indicating a score of 4 to 7 on this 10-point scale. The remaining 25% are not accounted for regarding their perception of stress since they feel it is not continuously high, moderate, or low. Current stressors include terrorism, paying bills, maintaining one’s health, keeping a job, and the economy.

Iona has been living with extremely stressful events, including the death of multiple family members, possibly some guilt since the family members were traveling to her home for the holidays, and dealing with her son who has Asperger autism. Now she also has the added stress of her husband losing his job. Iona will need to gain skills in managing stress and resources to assist her with her son as well as her own health. She should be referred to a psychologist and social worker who will be able to assist her in stress management. Otherwise these added stresses in her life will cause her to experience multiple exacerbations of her disease.

In 1910, when Sir William Osler delivered his Lumleian Lectures on “angina pectoris,” he described the relationship of stress and strain to angina pectoris. Approximately 15 years later, Walter Cannon, well known for his work in physiology, began to use the word stress in relation to his laboratory experiments on the “fight-or-flight” response. It seems possible that the term emerged from his work on the homeostatic features of living organisms and their tendency to “bound back” and “resist disruption” when acted on by an “external force.” At about the same time, Hans Selye, who became known for his research and publications on stress, began using the term...
stress in a very special way to mean an orchestrated set of bodily responses to any form of noxious stimulus.4 The content in this chapter has been organized into three sections: homeostasis, the stress response and adaptation to stress, and disorders of the stress response.

**HOMEOSTASIS**

After completing this section of the chapter, you should be able to meet the following objectives:

- Describe the concept of homeostasis.
- Describe the components of a control system, including the function of a negative feedback system.

The concepts of stress and adaptation have their origin in the complexity of the human body and the interactions between the body cells and its many organ systems. These interactions require that a level of homeostasis or constancy be maintained during the many changes that occur in the internal and external environments. In effecting a state of constancy, homeostasis requires feedback control systems that regulate cellular function and integrate the function of the different body systems.

**Constancy of the Internal Environment**

The environment in which body cells live is not the external environment that surrounds the organism, but rather the local fluid environment that surrounds each cell. Claude Bernard, a 19th century physiologist, was the first to describe clearly the central importance of a stable internal environment, which he termed the **milieu intérieur**. Bernard recognized that body fluids surrounding the cells (extracellular fluids) and the various organ systems provide the means for exchange between the external and the internal environments. It is from this internal environment that body cells receive their nourishment, and it is into this fluid that they secrete their wastes. Even the contents of the gastrointestinal tract and lungs do not become part of the internal environment until they have been absorbed into the extracellular fluid. A multicellular organism is able to survive only as long as the composition of the internal environment is compatible with the survival needs of the individual cells. For example, even a small change in the pH of the body fluids can disrupt the metabolic processes of the individual cells.

The concept of a stable internal environment was supported by Walter B. Cannon, who proposed that this kind of stability, which he called **homeostasis**, was achieved through a system of carefully coordinated physiologic processes that oppose change.5 Cannon pointed out that these processes were largely automatic and emphasized that homeostasis involves resistance to both internal and external disturbances.

In his book *Wisdom of the Body*, published in 1939, Cannon presented four tentative propositions to describe the general features of homeostasis.6 With this set of propositions, Cannon emphasized that when a factor is known to shift homeostasis in one direction, it is reasonable to expect the existence of mechanisms that have the opposite effect. In the homeostatic regulation of blood sugar, for example, mechanisms that both raise and lower blood sugar would be expected to play a part. As long as the responding mechanism to the initiating disturbance can recover homeostasis, the integrity of the body and the status of normality are retained.

**Control Systems**

The ability of the body to function and maintain homeostasis under conditions of change in the internal and external environment depends on the thousands of physiologic control systems that regulate body function. A homeostatic control system consists of a collection of interconnected components that function to keep a physical or chemical parameter of the body relatively constant. The body’s control systems regulate cellular function, control life processes, and integrate functions of the different organ systems.

Of recent interest have been the neuroendocrine control systems that influence behavior. Biochemical messengers that exist in our brain serve to control nerve activity, regulate information flow, and, ultimately, influence behavior.1 These control systems mediate the physical, emotional, and behavioral reactions to stressors that, taken together, are called the stress response.

Just like any control system, each stress response involves a sensor to detect the change, an integrator to sum all incoming data and compare it with “normal,” and effector(s) to try to reverse the change. For instance, a hiker’s eyes (sensor) see a snake (stressor). Her cerebral cortex (integrator) determines that the snake is a threat, and activates the heart, respiratory muscles, and many other organs (effectors) to assist her escape.

More complex stressors invoke more complex control systems, and sometimes the stress response cannot restore balance and homeostasis. For instance, negative physical and psychological experiences during the prenatal and childhood periods can impact one’s adult health.7 The impact may appear decades later, in the form of mental health issues, cancer, and even weakened bones. Therefore, it is important to identify early negative experiences and treat them, not only for the current health of the child but also for the future health of the adult.8

In addition, it is prudent for people to try to create a feeling of balance within, in order to improve neural circuitry, for example, by keeping a reflective journal of one’s interactions with people who may ordinarily stress them and describing how, applying new methods of communication both in talking with these people and responding to their questions, one may create a less stressful image of their daily interactions with a specific group of people. This should facilitate some physiological benefits.9 By trying to follow this advice, the brain will attempt to reorganize itself for the future by changing
the prefrontal cortex and restructuring its neural pathways. This increased neuroplasticity in the brain will improve emotional balance, flexibility, immune and cardiac function, and increase empathy ability. Results of studies also suggest assisting people in trying to remember their old experiences and taking some time to imagine possible future scenarios so they can be more prepared to manage future stressful experiences.

These studies validate the need for Iona to meet with a psychologist and a social worker who can assist her in stress management and possibly help her identify some past experience(s) that may need to be discussed. Working with these professionals may help her brain reorganize itself to deal more effectively with her son and his autism as well as managing appropriate rest times for herself.

**KEY POINTS**

**HOMEOSTASIS**

- Homeostasis is the purposeful maintenance of a stable internal environment by coordinated physiologic processes that oppose change.
- The physiologic control systems that oppose change operate by negative feedback mechanisms consisting of a sensor that detects a change, an integrator/comparator that sums and compares incoming data with a set point, and an effector system that returns the sensed function to within the range of the set point.

**Feedback Systems**

Most control systems in the body operate by negative feedback mechanisms, which function in a manner similar to the thermostat on a heating system. When the monitored function or value decreases below the set point of the system, the feedback mechanism causes the function or value to increase. When the function or value is increased above the set point, the feedback mechanism causes it to decrease (Fig. 9.1). For example, in the negative feedback mechanism that controls blood glucose levels, an increase in blood glucose stimulates an increase in insulin, which enhances the removal of glucose from the blood. When glucose has been taken up by cells and blood glucose levels fall, insulin secretion is inhibited and glucagon and other counterregulatory mechanisms stimulate the release of glucose from the liver, which causes the blood glucose to return to normal. The same is true for all endocrine organ hormones that are connected to the pituitary for their stimulating hormone and the hypothalamus for their releasing hormone. For example, when thyroxine (T4) in the thyroid is low, it triggers the pituitary to increase thyroid-stimulating hormone (TSH), which then increases with the purpose being to increase T4 secretion from the thyroid.

**IN SUMMARY**

Physiologic and psychological adaptation involves the ability to maintain the constancy of the internal environment (homeostasis) and behavior in the face of a wide range of changes in the internal and external environments. It involves control and negative feedback systems that regulate cellular function, control life's processes, regulate behavior, and integrate the function of the different body systems.

**STRESS AND ADAPTATION**

After completing this section of the chapter, you should be able to meet the following objectives:

- State Selye’s definition of stress.
- Explain the interactions among components of the nervous system in mediating the stress response.
- Describe the stress responses of the autonomic nervous system, the endocrine system, the immune system, and the musculoskeletal system.

The increased focus on health promotion has heightened interest in the roles of stress and biobehavioral stress responses in the development of disease. Stress may contribute directly to the production or exacerbation of a disease, or it may
contribute to the development of behaviors such as smoking, overeating, and drug abuse that increase the risk of disease.10

The Stress Response

In the early 1930s, the world-renowned endocrinologist Hans Selye was the first to describe a group of specific anatomic changes that occurred in rats that were exposed to a variety of different experimental stimuli. He came to an understanding that these changes were manifestations of the body’s attempt to adapt to stimuli. Selye described stress as “a state manifested by a specific syndrome of the body developed in response to any stimuli that made an intense systemic demand on it.” 11

As a young medical student, Selye noticed that patients with diverse disease conditions had many signs and symptoms in common. He observed, “whether a man suffers from a loss of blood, an infectious disease, or advanced cancer, he loses his appetite, his muscular strength, and his ambition to accomplish anything. Usually the patient also loses weight and even his facial expression betrays that he is ill.” 12 Selye referred to this as the “syndrome of just being sick.”

In his early career as an experimental scientist, Selye noted that a triad of adrenal enlargement, thymic atrophy, and gastric ulcers appeared in rats he was using for his studies. These same three changes developed in response to many different or nonspecific experimental challenges. He assumed that the hypothalamic–pituitary–adrenal (HPA) axis played a pivotal role in the development of this response. To Selye, the response to stressors was a process that enabled the rats to resist the experimental challenge by using the function of the system best able to respond to it. He labeled the response the general adaptation syndrome (GAS): general because the effect was a general systemic reaction, adaptive because the response was in reaction to a stressor, and syndrome because the physical manifestations were coordinated and dependent on each other.11

According to Selye, the GAS involves three stages: the alarm stage, the resistance stage, and the exhaustion stage. The alarm stage is characterized by a generalized stimulation of the sympathetic nervous system and the HPA axis, resulting in the release of catecholamines and cortisol. During the resistance stage, the body selects the most effective and economic channels of defense. During this stage, the increased cortisol levels, which were present during the first stage, drop because they are no longer needed. If the stressor is prolonged or overpowers the ability of the body to defend itself, the exhaustion stage ensues, during which resources are depleted and signs of “wear and tear” or systemic damage appear.13

Selye contended that many ailments, such as various emotional disturbances, mildly annoying headaches, insomnia, upset stomach, gastric and duodenal ulcers, certain types of rheumatic disorders, and cardiovascular and kidney diseases, appear to be initiated or encouraged by the “body itself because of its faulty adaptive reactions to potentially injurious agents.”12

With a new diagnosis of SLE, Iona is manifesting the last stage of the stress response. She has certainly depleted many of her body’s resources and is experiencing “wear and tear” and systemic damage, such as renal disease and some type of joint inflammatory disorder.

The events or environmental agents responsible for initiating the stress response were called stressors. According to Selye, stressors could be endogenous, arising from within the body, or exogenous, arising from outside the body.12 In explaining the stress response, Selye proposed that two factors determine the nature of the stress response—the properties of the stressor and the conditioning of the person being stressed. Selye indicated that not all stress was detrimental; hence, he coined the terms eustress and distress.13 He suggested that mild, brief, and controllable periods of stress could be perceived as positive stimuli to emotional and intellectual growth and development. It is the severe, protracted, and uncontrolled situations of psychological and physical distress that are disruptive of health.12 For example, the joy of becoming a new parent and the sorrow of losing a parent are completely different experiences, yet their stressor effect—the nonspecific demand for adjustment to a new situation—can be similar.

It is increasingly clear that the physiologic stress response is far more complicated than can be explained fully by a classic stimulus–response mechanism. Stressors tend to produce different responses in different people or in the same person at different times, indicating the influence of the adaptive capacity of the person, or what Selye called conditioning factors. These conditioning factors may be internal (e.g., genetic predisposition, age, sex) or external (e.g., exposure to environmental agents, life experiences, dietary factors, level of social support).12 The relative risk for development of a stress-related pathologic process seems, at least in part, to depend on these factors.

Richard Lazarus, a well-respected psychologist who devoted his career to the study of stress and emotions, considered “meanings and values to be at the center of human life and to represent the essence of stress, emotion and adaptation.”14 There is evidence that the hypothalamic–pituitary–adrenocortical axis, the adrenomedullary hormonal system, and the sympathetic nervous system are differentially activated depending on the type and intensity of the stressor.15

Iona has two internal conditioning factors for SLE, such as being female and in her late thirties. She also has external conditioning factors, such as life experiences and level of social support. With so many stressors in her life, she is most vulnerable for the stress response to go awry.

Neuroendocrine Responses

The manifestations of the stress response are strongly influenced by both the nervous and endocrine systems. The neuroendocrine systems integrate signals received along neurosensory
pathways and from circulating mediators that are carried in the bloodstream. In addition, the immune system both affects and is affected by the stress response. Table 9.1 summarizes the action of hormones involved in the neuroendocrine responses to stress. The results of the coordinated release of these neurohormones include the mobilization of energy, a sharpened focus and awareness, increased cerebral blood flow and glucose utilization, enhanced cardiovascular and respiratory functioning, redistribution of blood flow to the brain and muscles, modulation of the immune response, inhibition of reproductive function, and a decrease in appetite.\(^{13}\)

The stress response is a normal, coordinated physiologic system meant to increase the probability of survival, but also designed to be an acute response—turned on when necessary to bring the body back to a stable state and turned off when the challenge to homeostasis abates. Therefore, under normal circumstances, the neural responses and the hormones that are released during the response do not persist long enough to cause damage to vital tissues. Since the early 1980s, the term *allostasis* has been used by some investigators to describe the physiologic changes in the neuroendocrine, autonomic, and immune systems that occur in response to either real or perceived challenges to homeostasis. The persistence or accumulation of these allostatic changes (e.g., immunosuppression, activation of the sympathetic nervous and renin–angiotensin–aldosterone systems) has been called an *allostatic load*, and this concept has been used to measure the cumulative effects of stress on humans.\(^{16}\)

The integration of the components of the stress response, which occurs at the level of the central nervous system (CNS), is complex and not completely understood. It relies on communication along neuronal pathways of the cerebral cortex, the limbic system, the thalamus, the hypothalamus, the pituitary gland, and the reticular activating system (RAS; Fig. 9.2). The cerebral cortex is involved with vigilance, cognition, and focused attention and the limbic system with the emotional components (e.g., fear, excitement, rage, anger) of the stress response. The thalamus functions as the relay center and is important in receiving, sorting out, and distributing sensory input. The hypothalamus coordinates the responses of the endocrine and autonomic nervous systems (ANS). The RAS modulates mental alertness, ANS activity, and skeletal muscle tone, using input from other neural structures. The musculoskeletal tension that occurs during the stress response reflects increased activity of the RAS and its influence on the reflex circuits that control muscle tone. Adding to the complexity of this system is the fact that the individual brain circuits that participate in the mediation of the stress response interact and regulate the activity of each other. For example, reciprocal connections exist between neurons in the hypothalamus that initiate release of corticotropin-releasing factor (CRF) and neurons in the locus caeruleus (LC) associated with release of norepinephrine (NE). Thus, NE stimulates the secretion of CRF, and CRF stimulates the release of NE.\(^{16}\)

**Locus Caeruleus.** Central to the neural component of the neuroendocrine response to stress is an area of the brain stem called the *locus caeruleus*.\(^{16}\) The LC is densely populated with neurons that produce NE and is thought to be the central integrating site for the ANS response to stressful stimuli (Fig. 9.3). The LC–NE system has afferent pathways to the

| TABLE 9.1 HORMONES INVOLVED IN THE NEUROENDOCRINE RESPONSES TO STRESS |
|---------------------------------|-------------------|----------------------------------|
| **HORMONES ASSOCIATED WITH THE STRESS RESPONSE** | **SOURCE OF THE HORMONE** | **PHYSIOLOGIC EFFECTS** |
| Catecholamines (NE, epinephrine) | LC, adrenal medulla | Produces a decrease in insulin release and an increase in glucagon release resulting in increased glycogenolysis, gluconeogenesis, lipolysis, proteolysis, and decreased glucose uptake by the peripheral tissues; an increase in heart rate, cardiac contractility, and vascular smooth muscle contraction; and relaxation of bronchial smooth muscle. |
| Corticotropin-releasing factor (CRF) | Hypothalamus | Stimulates ACTH release from the anterior pituitary and increased activity of the LC neurons. |
| Adrenocorticotropic hormone (ACTH) | Anterior pituitary | Stimulates the synthesis and release of cortisol. |
| Glucocorticoid hormones (e.g., cortisol) | Adrenal cortex | Potentiates the actions of epinephrine and glucagon; inhibits the release and/or actions of the reproductive hormones and thyroid-stimulating hormone; and produces a decrease in immune cells and inflammatory mediators. |
| Mineralocorticoid hormones (e.g., aldosterone) | Adrenal cortex | Increases sodium absorption by the kidney. |
| Antidiuretic hormone (ADH, vasopressin) | Hypothalamus, posterior pituitary | Increases water absorption by the kidney; produces vasoconstriction of blood vessels; and stimulates the release of ACTH. |
Corticotropin-Releasing Factor. CRF is central to the endocrine component of the neuroendocrine response to stress (see Fig. 9.3). CRF is a small peptide hormone found in both the hypothalamus and in extra hypothalamic structures, such as the limbic system and the brain stem. It is both an important endocrine regulator of pituitary and adrenal activity and a neurotransmitter involved in ANS activity, metabolism, and behavior. Receptors for CRF are distributed throughout the brain as well as many peripheral sites. CRF from the hypothalamus induces secretion of adrenocorticotropic hormone (ACTH) from the anterior pituitary gland. ACTH, in turn, stimulates the adrenal gland to synthesize and secrete the glucocorticoid hormones (e.g., cortisol).

The glucocorticoid hormones have a number of direct or indirect physiologic effects that mediate the stress response, enhance the action of other stress hormones, or suppress other components of the stress system. In this regard, cortisol acts not only as a mediator of the stress response but as an inhibitor, such that overactivation of the stress response does not occur. Cortisol maintains blood glucose levels by antagonizing the effects of insulin and enhances the effect of catecholamines on the cardiovascular system. It also suppresses osteoblast activity, hematopoiesis, protein and collagen synthesis, and immune responses. All of these functions are meant to protect the organism against...
the effects of a stressor and to focus energy on regaining balance in the face of an acute challenge to homeostasis.

**Angiotensin II.** Stimulation of the sympathetic nervous system also activates the peripheral renin–angiotensin–aldosterone system (RAAS), which mediates a peripheral increase in vascular tone and renal retention of sodium and water. These changes contribute to the physiologic changes that occur with the stress response and, if prolonged, may contribute to pathologic changes. Angiotensin II, peripherally delivered or locally produced, also has CNS effects; angiotensin II type 1 (AT₁) receptors are widely distributed in the hypothalamus and LC. Through these receptors, angiotensin II enhances CRF formation and release, contributes to the release of ACTH from the pituitary, enhances stress-induced release of vasopressin from the posterior pituitary, and stimulates the release of NE from the LC.16

**Other Hormones.** A wide variety of other hormones, including growth hormone, thyroid hormone, and the reproductive hormones, also are responsive to stressful situations. Systems responsible for reproduction, growth, and immunity are directly linked to the stress system, and the hormonal effects of the stress response profoundly influence these systems.

Although growth hormone is initially elevated at the onset of stress, the prolonged presence of cortisol leads to suppression of growth hormone, insulin-like growth factor 1 (IGF-1), and other growth factors, exerting a chronically inhibitory effect on growth. In addition, CRF directly increases somatostatin, which in turn inhibits growth hormone secretion. Although the connection is speculative, the effects of stress on growth hormone may provide one of the vital links to understanding failure to thrive in children.

Stress-induced cortisol secretion also is associated with decreased levels of thyroid-stimulating hormone and inhibition of conversion of thyroxine (T4) to the more biologically active triiodothyronine (T₃) in peripheral tissues. Both changes may serve as a means to conserve energy at times of stress.

Antidiuretic hormone (ADH) released from the posterior pituitary is also involved in the stress response, particularly in hypotensive stress or stress due to fluid volume loss. ADH, also known as vasopressin, increases water retention by the kidneys and produces vasoconstriction of blood vessels. In addition, vasopressin synthesized in parvocellular neurons of the hypothalamus and transported to the anterior pituitary appears to synergize the capacity of CRF to stimulate the release of ACTH.

The neurotransmitter serotonin or 5-hydroxytryptamine (5-HT) also plays a role in the stress response through neurons that innervate the hypothalamus, amygdala, and other limbic structures. Administration of 5-HT receptor agonists to laboratory animals was shown to increase the secretion of several stress hormones. Other hormones that have a possible role in the stress response include vasopressin, increased corticosteroid production and atrophy of the thymus that are known to suppress the immune response. In concert, these two components of the stress system, through endocrine and...
neurotransmitter pathways, produce the physical and behavioral changes designed to adapt to acute stress. Much of the literature regarding stress and the immune response focuses on the causal role of stress in immune-related diseases. It has also been suggested that the reverse may occur. That is, emotional and psychological manifestations of the stress response may be a reflection of alterations in the CNS resulting from the immune response (see Fig. 9.3). Immune cells such as monocytes and lymphocytes can penetrate the blood–brain barrier and take up residence in the brain, where they secrete chemical messengers called cytokines that influence the stress response.

The exact mechanism by which stress produces its effect on the immune response is unknown and probably varies from person to person, depending on genetic and environmental factors. The most significant arguments for interaction between the neuroendocrine and immune systems derive from evidence that the immune and neuroendocrine systems share common signal pathways (i.e., messenger molecules and receptors), that hormones and neuromediators can alter the function of immune cells, and that the immune system and its mediators can modulate neuroendocrine function. Receptors for a number of CNS-controlled hormones and neuromediators reportedly have been found on lymphocytes. Among these are receptors for glucocorticoids, insulin, testosterone, prolactin, catecholamines, estrogens, acetylcholine, and growth hormone, suggesting that these hormones and neuromediators influence lymphocyte function. For example, cortisol is known to suppress immune function, and pharmacologic doses of cortisol are used clinically to suppress the immune response. It has been observed that the HPA axis is activated by cytokines such as interleukin-1, interleukin-6, and tumor necrosis factor that are released from immune cells.

With SLE there is an increase in lymphocytes, and these can migrate to the brain where they secrete cytokines, which trigger inflammation. Also the immunological system can be modulated to recognize one’s own cells as antigens and destroy their own cells. This is seen in the autoimmune disorder, SLE (Iona’s diagnosis).

A second possible route for neuroendocrine regulation of immune function is through the sympathetic nervous system and the release of catecholamines. The lymph nodes, thymus, and spleen are supplied with ANS nerve fibers. Centrally acting CRF activates the ANS through multisynaptic descending pathways, and circulating epinephrine acts synergistically with CRF and cortisol to inhibit the function of the immune system.

Not only is the quantity of immune expression changed because of stress, but the quality of the response is changed. Stress hormones differentially stimulate the proliferation of subtypes of T lymphocyte helper cells. Because these T helper cell subtypes secrete different cytokines, they stimulate different aspects of the immune response. One subtype tends to stimulate T lymphocytes and the cellular-mediated immune response, whereas a second type tends to activate B lymphocytes and humoral-mediated immune responses.

Coping and Adaptation to Stress

The ability to adapt to a wide range of environments and stressors is not peculiar to humans. According to René Dubos (a microbiologist noted for his study of human responses to the total environment), “adaptability is found throughout life and is perhaps the one attribute that distinguishes most clearly the world of life from the world of inanimate matter.”

Living organisms, no matter how primitive, do not submit passively to the impact of environmental forces. They attempt to respond adaptively, each in its own unique and most suitable manner. The higher the organism is on the evolutionary scale, the larger its repertoire of adaptive mechanisms and its ability to select and limit aspects of the environment to which it responds. The most fully evolved mechanisms are the social responses through which people or groups modify their environments, their habits, or both to achieve a way of life that is best suited to their needs.

Adaptation

Human beings, because of their highly developed nervous system and intellect, usually have alternative mechanisms for adapting and have the ability to control many aspects of their environment. Air conditioning and central heating limit the need to adapt to extreme changes in environmental temperature. The availability of antiseptic agents, immunizations, and antibiotics eliminates the need to respond to common infectious agents. At the same time, modern technology creates new challenges for adaptation and provides new sources of stress, such as noise and air pollution, increased exposure to harmful chemicals, and changes in biologic rhythms imposed by shift work and global travel.

Of particular interest are the differences in the body’s response to events that threaten the integrity of the body’s
physiologic environment and those that threaten the integrity of the person’s psychosocial environment. Many of the body’s responses to physiologic disturbances are controlled on a moment-by-moment basis by feedback mechanisms that limit their application and duration of action. For example, the baroreflex-mediated rise in heart rate that occurs when a person moves from the recumbent to the standing position is almost instantaneous and subsides within seconds. Furthermore, the response to physiologic disturbances that threaten the integrity of the internal environment is specific to the threat; the body usually does not raise the body temperature when an increase in heart rate is needed. In contrast, the response to psychological disturbances is not regulated with the same degree of specificity and feedback control. Instead, the effect may be inappropriate and sustained.

Factors Affecting the Ability to Adapt
Adaptation implies that an individual has successfully created a new balance between the stressor and the ability to deal with it. The means used to attain this balance are called coping strategies or coping mechanisms. Coping mechanisms are the emotional and behavioral responses used to manage threats to our physiologic and psychological homeostasis. According to Lazarus, how we cope with stressful events depends on how we perceive and interpret the event. Is the event perceived as a threat of harm or loss? Is the event perceived as a challenge rather than a threat? Physiologic reserve, time, genetics, age, health status, nutrition, sleep–wake cycles, hardiness, and psychosocial factors influence a person’s appraisal of a stressor and the coping mechanisms used to adapt to the new situation (Fig. 9.4).

Physiologic and Anatomic Reserve. The trained athlete is able to increase cardiac output six- to sevenfold during exercise. The safety margin for adaptation of most body systems is considerably greater than that needed for normal activities. The red blood cells carry more oxygen than the tissues can use, the liver and fat cells store excess nutrients, and bone tissue stores calcium in excess of that needed for normal neuromuscular function. The ability of body systems to increase their function given the need to adapt is known as the physiologic reserve. Many of the body organs, such as the lungs, kidneys, and adrenals, are paired to provide anatomic reserve as well. Both organs are not needed to ensure the continued existence and maintenance of the internal environment. Many people function normally with only one lung or one kidney. In kidney disease, for example, signs of renal failure do not occur until approximately 80% of the functioning nephrons have been destroyed.

Time. Adaptation is most efficient when changes occur gradually rather than suddenly. It is possible, for instance, to lose a liter or more of blood through chronic gastrointestinal bleeding over a week without manifesting signs of shock. However, a sudden hemorrhage that causes rapid loss of an equal amount of blood is likely to cause hypotension and shock.

Genetics. Adaptation is further affected by the availability of adaptive responses and flexibility in selecting the most appropriate and economical response. The greater the number of available responses, the more effective is the capacity to adapt. Genetics can ensure that the systems that are essential to adaptation function adequately. Even a gene that has detrimental effects may prove adaptive in some environments. In Africa, the gene for sickle cell anemia persists in some populations because it provides some resistance to infection with the parasite that causes malaria.

Age. The capacity to adapt is decreased at the extremes of age. The ability to adapt is impaired by the immaturity of an infant, much as it is by the decline in functional reserve that occurs with age. For example, the infant has difficulty concentrating urine because of immature renal structures and therefore is less able than an adult to cope with decreased water intake or exaggerated water losses. A similar situation exists in the elderly owing to age-related changes in renal function.

Gender. Within the last decade, primarily because females have been included in basic science and clinical investigations, differences between the sexes in cardiovascular, respiratory, endocrine, renal, and neurophysiologic function have been found, and it has been hypothesized that sex hormones are the basis of these biologic differences. Technological advances in cellular and molecular biology have made it clear, however, that there are fundamental differences in the locale and regulation of individual genes in the male and female genome. These differences have general implications for the prevention, diagnosis, and treatment of disease and specific implications for our understanding of the sex-based differences in response to life’s stressors.

Given the nature of sex-based differences, it is not surprising that there are differences in the physiologic stress
response in both the HPA axis and in the ANS. Premenopausal women tend to have a lower activation of the sympathetic nervous system than men in response to stressors. Gender-based differences in activation of the stress response may partially explain differences in susceptibility to diseases in which the stress response may play a causal role. These research results are not definitive but are intriguing and can serve as a springboard for further research.

**Health Status.** Physical and mental health status determines physiologic and psychological reserves and is a strong determinant of the ability to adapt. For example, people with heart disease are less able to adjust to stresses that require the recruitment of cardiovascular responses. Severe emotional stress often produces disruption of physiologic function and limits the ability to make appropriate choices related to long-term adaptive needs. Those who have worked with acutely ill people know that the will to live often has a profound influence on survival during life-threatening illnesses.

**Nutrition.** There are 50 to 60 essential nutrients, including minerals, lipids, certain fatty acids, vitamins, and specific amino acids. Deficiencies or excesses of any of these nutrients can alter a person’s health status and impair the ability to adapt. The importance of nutrition to enzyme function, immune response, and wound healing is well known. On a worldwide basis, malnutrition may be one of the most common causes of immunodeficiency.

Among the problems associated with dietary excess are obesity and alcohol abuse. Obesity is a common problem. It predisposes a person to a number of health problems, including atherosclerosis and hypertension. Alcohol is commonly used in excess. It acutely affects brain function and, with long-term use, can seriously impair the function of the liver, brain, and other vital structures.

**Sleep–Wake Cycles.** Sleep is considered to be a restorative function in which energy is restored and tissues are regenerated. Sleep occurs in a cyclic manner, alternating with periods of wakefulness and increased energy use. Biologic rhythms play an important role in adaptation to stress, development of illness, and response to medical treatment. Many rhythms such as rest and activity, work and leisure, and eating and drinking oscillate with a frequency similar to that of the 24-hour light–dark solar day. The term *circadian*, from the Latin *circa* (“about”) and *dies* (“day”), is used to describe these 24-hour diurnal rhythms.

Sleep disorders and alterations in the sleep–wake cycle have been shown to alter immune function, the normal circadian pattern of hormone secretion, and physical and psychological functioning. The two most common manifestations of an alteration in the sleep–wake cycle are insomnia and sleep deprivation or increased somnolence. In some people, stress may produce sleep disorders, and in others, sleep disorders may lead to stress. Acute stress and environmental disturbances, loss of a loved one, recovery from surgery, and pain are common causes of transient and short-term insomnia. Air travel and jet lag constitute additional causes of altered sleep–wake cycles, as does shift work.

**Hardiness.** Studies by social psychologists have focused on individuals’ emotional reactions to stressful situations and their coping mechanisms to determine those characteristics that help some people remain healthy despite being challenged by high levels of stressors. For example, the concept of hardiness describes a personality characteristic that includes a sense of having control over the environment, a sense of having a purpose in life, and an ability to conceptualize stressors as a challenge rather than a threat. Many studies by nurses and social psychologists suggest that hardiness is correlated with positive health outcomes.

**Psychosocial Factors.** Several studies have related social factors and life events to illness. Scientific interest in the social environment as a cause of stress has gradually broadened to include the social environment as a resource that modulates the relation between stress and health. Presumably, people who can mobilize strong supportive resources from within their social relationships are better able to withstand the negative effects of stress on their health.

Close relationships with others can involve positive effects as well as the potential for conflict and may, in some situations, leave the person less able to cope with life stressors.

---

**IN SUMMARY**

The stress response involves the activation of several physiologic systems (sympathetic nervous system, the HPA axis, and the immune system) that work in a coordinated fashion to protect the body against damage from the intense demands made on it. Selye called this response the *general adaptation syndrome*. The stress response is divided into three stages: the *alarm stage*, with activation of the sympathetic nervous system and the HPA axis; the *resistance stage*, during which the body selects the most effective defenses; and the *exhaustion stage*, during which physiologic resources are depleted and signs of systemic damage appear.

The activation and control of the stress response are mediated by the combined efforts of the nervous and endocrine systems. The neuroendocrine systems integrate signals received along neurosensory pathways and from circulating mediators that are carried in the bloodstream. In addition, the immune system both affects and is affected by the stress response.

Adaptation is affected by a number of factors, including experience and previous learning, the rapidity with which the need to adapt occurs, genetic endowment and age, health status, nutrition, sleep–wake cycles, hardiness, and psychosocial factors.
For the most part, the stress response is meant to be acute and time limited. The time-limited nature of the process renders the accompanying catabolic and immunosuppressive effects advantageous. It is the chronicity of the response that is thought to be disruptive to physical and mental health.

Stressors can assume a number of patterns in relation to time. They may be classified as acute time limited, chronic intermittent, or chronic sustained. An acute time-limited stressor is one that occurs over a short time and does not recur. A chronic intermittent stressor is one to which a person is chronically exposed. The frequency or chronicity of circumstances to which the body is asked to respond often determines the availability and efficiency of the stress responses. The response of the immune system, for example, is more rapid and efficient on second exposure to a pathogen than it is on first exposure. However, chronic exposure to a stressor can fatigue the system and impair its effectiveness.

**Effects of Acute Stress**

The reactions to acute stress are those associated with the ANS, the fight-or-flight response. The manifestations of the stress response—a pounding headache; a cold, moist skin; and a stiff neck—are all part of the acute stress response. Centrally, there is facilitation of neural pathways mediating arousal, alertness, vigilance, cognition, and focused attention, as well as appropriate aggression. The acute stress response can result from either psychologically or physiologically threatening events. In situations of life-threatening trauma, these acute responses may be lifesaving in that they divert blood from less essential to more essential body functions. Increased alertness and cognitive functioning enable rapid processing of information and arrival at the most appropriate solution to the threatening situation.

However, for people with limited coping abilities, either because of physical or mental health, the acute stress response may be detrimental (Table 9.2). This is true of people with preexisting heart disease in whom the overwhelming sympathetic behaviors associated with the stress response can lead to arrhythmias. For people with other chronic health problems, such as headache disorder, acute stress may precipitate a recurrence. In healthy people, the acute stress response can redirect attention from behaviors that promote health, such as attention to proper meals and getting adequate sleep. For those with health problems, it can interrupt compliance with medication regimens and exercise programs. In some situations, the acute arousal state actually can be life-threatening, physically immobilizing the person when movement would avert catastrophe (e.g., moving out of the way of a speeding car).

**Effects of Chronic Stress**

The stress response is designed to be an acute self-limited response in which activation of the ANS and the HPA axis is controlled in a negative feedback manner. As with all negative feedback systems, pathophysiologic changes can occur in the stress response system. Function can be altered in several ways, including when a component of the system fails; when the neural and hormonal connections among the components of the system are dysfunctional; and when the original stimulus for the activation of the system is prolonged or of such magnitude that it overwhelms the ability of the system to respond appropriately. In these cases, the system may become overactive or underactive.

Chronicity and excessive activation of the stress response can result from chronic illnesses as well as contribute to the development of long-term health problems. Chronic activation of the stress response is an important public health issue from both a health and a cost perspective. Stress is linked to a myriad of health disorders, such as diseases of the cardiovascular, gastrointestinal, immune, and neurologic systems, as well as depression, chronic alcoholism and drug abuse, eating disorders, accidents, and suicide.

**Posttraumatic Stress Disorder**

Posttraumatic stress disorder (PTSD) is seen frequently. It is characterized by a severe stress response secondary to experiencing previous trauma. The person may remember the traumatic event, or PTSD may occur with no recollection of an earlier stressful experience. PTSD that is manifested 6 months

For the most part, the stress response is meant to be acute and time limited. The time-limited nature of the process renders the accompanying catabolic and immunosuppressive effects advantageous. It is the chronicity of the response that is thought to be disruptive to physical and mental health.

Stressors can assume a number of patterns in relation to time. They may be classified as acute time limited, chronic intermittent, or chronic sustained. An acute time-limited stressor is one that occurs over a short time and does not recur. A chronic intermittent stressor is one to which a person is chronically exposed. The frequency or chronicity of circumstances to which the body is asked to respond often determines the availability and efficiency of the stress responses. The response of the immune system, for example, is more rapid and efficient on second exposure to a pathogen than it is on first exposure. However, chronic exposure to a stressor can fatigue the system and impair its effectiveness.

**Effects of Acute Stress**

The reactions to acute stress are those associated with the ANS, the fight-or-flight response. The manifestations of the stress response—a pounding headache; a cold, moist skin; and a stiff neck—are all part of the acute stress response. Centrally, there is facilitation of neural pathways mediating arousal, alertness, vigilance, cognition, and focused attention, as well as appropriate aggression. The acute stress response can result from either psychologically or physiologically threatening events. In situations of life-threatening trauma, these acute responses may be lifesaving in that they divert blood from less essential to more essential body functions. Increased alertness and cognitive functioning enable rapid processing of information and arrival at the most appropriate solution to the threatening situation.

However, for people with limited coping abilities, either because of physical or mental health, the acute stress response may be detrimental (Table 9.2). This is true of people with preexisting heart disease in whom the overwhelming sympathetic behaviors associated with the stress response can lead to arrhythmias. For people with other chronic health problems, such as headache disorder, acute stress may precipitate a recurrence. In healthy people, the acute stress response can redirect attention from behaviors that promote health, such as attention to proper meals and getting adequate sleep. For those with health problems, it can interrupt compliance with medication regimens and exercise programs. In some situations, the acute arousal state actually can be life-threatening, physically immobilizing the person when movement would avert catastrophe (e.g., moving out of the way of a speeding car).

**Effects of Chronic Stress**

The stress response is designed to be an acute self-limited response in which activation of the ANS and the HPA axis is controlled in a negative feedback manner. As with all negative feedback systems, pathophysiologic changes can occur in the stress response system. Function can be altered in several ways, including when a component of the system fails; when the neural and hormonal connections among the components of the system are dysfunctional; and when the original stimulus for the activation of the system is prolonged or of such magnitude that it overwhelms the ability of the system to respond appropriately. In these cases, the system may become overactive or underactive.

Chronicity and excessive activation of the stress response can result from chronic illnesses as well as contribute to the development of long-term health problems. Chronic activation of the stress response is an important public health issue from both a health and a cost perspective. Stress is linked to a myriad of health disorders, such as diseases of the cardiovascular, gastrointestinal, immune, and neurologic systems, as well as depression, chronic alcoholism and drug abuse, eating disorders, accidents, and suicide.

**Posttraumatic Stress Disorder**

Posttraumatic stress disorder (PTSD) is seen frequently. It is characterized by a severe stress response secondary to experiencing previous trauma. The person may remember the traumatic event, or PTSD may occur with no recollection of an earlier stressful experience. PTSD that is manifested 6 months
after the traumatic event is called PTSD with delayed onset. \(^22\)

PTSD was formerly called battle fatigue or shell shock because it was first characterized in soldiers returning from combat. Although war is still a significant cause of PTSD, other major catastrophic events, such as weather-related disasters (hurricanes, earthquakes, and floods), airplane crashes, terrorist bombings, and rape or child abuse, also may result in development of the disorder. People who are exposed to traumatic events are also at risk for development of major depression, panic disorder, generalized anxiety disorder, and substance abuse. \(^22\) They may also have physical symptoms and illnesses (e.g., hypertension, asthma, and chronic pain syndromes).

PTSD is characterized by a constellation of symptoms that are experienced as states of intrusion, avoidance, and hyperarousal. **Intrusion** refers to the occurrence of “flashbacks” during waking hours or nightmares in which the past traumatic event is relived, often in vivid and frightening detail. **Avoidance** refers to the emotional numbing that accompanies this disorder and disrupts important personal relationships. Because a person with PTSD has not been able to resolve the painful feelings associated with the trauma, depression is commonly a part of the clinical picture. Survivor guilt also may be a product of traumatic situations in which the person survived the disaster but loved ones did not. **Hyperarousal** refers to the presence of increased irritability, difficulty concentrating, an exaggerated startle reflex, and increased vigilance and concern over safety. In addition, memory problems, sleep disturbances, and excessive anxiety are commonly experienced by people with PTSD.

For a diagnosis of PTSD to be made, the person must have experienced, witnessed, or confronted a traumatic event, which caused a response in the person involving horror and fear. The triad of symptoms of intrusion, avoidance, and hyperarousal that characterize PTSD must be present together for at least 1 month, and the disorder must have caused clinically significant distress. \(^22\) Although the pathophysiology of PTSD is not completely understood, the revelation of physiologic changes related to the disorder has shed light on why some people recover from the disorder, whereas others do not. It has been hypothesized that the intrusive symptoms of PTSD may arise from exaggerated sympathetic nervous system activation in response to the traumatic event. People with chronic PTSD have been shown to have increased levels of NE and increased activity of \(\alpha_2\)-adrenergic receptors.

Recent neuroanatomic studies have identified alterations in two brain structures (the amygdala and hippocampus). Positron emission tomography and functional magnetic resonance imaging have shown increased reactivity of the amygdala and hippocampus and decreased reactivity of the anterior cingulate and orbitofrontal areas. These areas of the brain are involved in fear responses. The hippocampus also functions in memory processes. Differences in hippocampal function and memory processes suggest a neuroanatomic basis for the intense problems suffered by people diagnosed with PTSD. People with PTSD demonstrate decreased cortisol levels, increased sensitivity of cortisol receptors, and an enhanced negative feedback inhibition of cortisol release with the dexamethasone suppression test. Dexamethasone is a synthetic glucocorticoid that mimics the effects of cortisol and directly inhibits the action of CRF and ACTH. The hypersuppression of cortisol observed with the dexamethasone test suggests that persons with PTSD do not exhibit a classic stress response as described by Selye. Because this hypersuppression has not been described in other psychiatric disorders, it may serve as a relatively specific marker for PTSD.

Little is known about the risk factors that predispose people to the development of PTSD. Statistics indicate there is a need for studies to determine risk factors for PTSD as a means of targeting people who may need intensive therapeutic measures after a life-threatening event. Research also is needed to determine the mechanisms by which the disorder develops so that it can be prevented or, if that is not possible, so that treatment methods can be developed to decrease the devastating effects of this disorder on affected people and their families. \(^23\)

Health care professionals need to be aware that people who present with symptoms of depression, anxiety, and alcohol or drug abuse may in fact be suffering from PTSD. The patient history should include questions concerning the occurrence of violence, major loss, or traumatic events in the person’s life.

Debriefing, or talking about the traumatic event at the time it happens, often is an effective therapeutic tool. Crisis teams are often among the first people to attend to the emotional needs of those caught in catastrophic events. Some people may need continued individual or group therapy. Often concurrent pharmacotherapy with antidepressant and antianxiety agents is useful and helps the person participate more fully in therapy.

Most importantly, the person with PTSD should not be made to feel responsible for the disorder or that it is evidence of a so-called character flaw. It is not uncommon for people with this disorder to be told to “get over it” or “just get on with it, because others have.” There is ample evidence to suggest that there is a biologic basis for the individual differences in responses to traumatic events, and these differences need to be taken into account.

**Treatment and Research of Stress Disorders**

The change that occurs in the biochemical stress response system of people who have experienced some type of mistreatment as a child so that they are not able to respond effectively to stressors in the future is called the traumatic stress response. \(^24\) Evidence supports that early intervention can assist the person in adapting new and effective coping mechanisms to better manage stress in the future. \(^24\) Additionally, a study conducted with caregivers of a spouse or family member demonstrates that those who reported higher levels of caregiver stress also had poorer self-perceived health. When early interventions for stress management were given to these caregivers, there were less negative self-identified behaviors. \(^25\) Several studies have supported the use of early interventions to assist in managing stress. In fact, one study describes how resilience development was conducted with oncology nurses to decrease their burnout. Findings of the study indicated the program was successful and recommended to be implemented for all nurses. \(^26\)
Treatment

The treatment of stress should be directed toward helping people avoid coping behaviors that impose a risk to their health and providing them with alternative stress-reducing strategies. People who are overwhelmed by the number of life stressors to which they have been exposed can use purposeful priority setting and problem solving. Other nonpharmacologic methods used for stress reduction are relaxation techniques, guided imagery, music therapy, massage, and biofeedback.

Relaxation. Practices for evoking the relaxation response are numerous. They are found in virtually every culture and are credited with producing a generalized decrease in sympathetic system activity and musculoskeletal tension.

Progressive muscle relaxation is one method of relieving tension. Tension can be defined physiologically as the inappropriate contraction of muscle fibers. Progressive muscle relaxation, which has been modified by a number of therapists, consists of systematic contraction and relaxation of major muscle groups.2 As the person learns to relax, the various muscle groups are combined. Eventually, the person learns to relax individual muscle groups without first contracting them.

Imagery. Guided imagery is another technique that can be used to achieve relaxation. One method is scene visualization, in which the person is asked to sit back, close the eyes, and concentrate on a scene narrated by the therapist. Whenever possible, all five senses are involved. The person attempts to see, feel, hear, smell, and taste aspects of the visual experience. Other types of imagery involve imagining the appearance of each of the major muscle groups and how they feel during tension and relaxation.

Music Therapy. Music therapy is used for both its physiologic and psychological effects. It involves listening to selected pieces of music as a means of ameliorating anxiety or stress, reducing pain, decreasing feelings of loneliness and isolation, buffering noise, and facilitating expression of emotion. Music therapy is selected based on a person’s musical preference and past experiences with music. Depending on the setting, headphones may be used to screen out other distracting noises. Radio and television music is inappropriate for music therapy because of the inability to control the selection of pieces that are played, the interruptions that occur (e.g., commercials and announcements), and the quality of the reception.

Biofeedback. Biofeedback is a technique in which a person learns to control physiologic functioning. It involves electronic monitoring of one or more physiologic responses to stress with immediate feedback of the specific response to the person undergoing treatment.

Research

Research in stress has focused on personal reports of the stress situation and the physiologic responses to stress. A number of interview guides and written instruments are available for measuring the personal responses to stress and coping in adults. Measurements of vital signs, ACTHs, glucocorticoids (cortisol) and glucose levels, and immunological counts are all part of current research studies involving stress.

People who are critically ill and on ventilators were assigned to listen to music or not were studied regarding their vital signs and sedation levels (Ramsay Sedation Scale). All were medicated with the same sedative and dosed according to weight. The experimental group (those who were given music) had higher levels of sedation as evidenced by higher Ramsay scores than those in the control group, although there was no difference in vital signs. Having maintained higher levels of sedation on the Ramsay Sedation Scale was deemed to be a positive outcome for preventing stress. A study conducted with Puerto Rican women living in the United States showed that many experienced stress as evidenced by increased respiratory rate, heart rate, and blood pressure. These women were found to have a statistically significantly higher chance to develop cardiovascular disease, arthritis, abdominal obesity, hypertension, and diabetes mellitus in the future. Evidence from another study illustrates that Ecuadorian women with high stress are developing SLE, which is an autoimmune disorder that causes systemic inflammation.

Research that attempts to establish a link between the stress response and disease needs to be interpreted with caution owing to the influence that individual differences have in the way people respond to stress. Not everyone who experiences stressful life events develops a disease. The evidence for a link between the stress response system and the development of disease in susceptible people is compelling but not conclusive. No study has established a direct cause-and-effect relationship between the stress response and disease occurrence. For example, depressive illness often is associated with an increase in both plasma cortisol and cerebrospinal fluid concentrations of CRF. The question that arises is whether this increased plasma cortisol is a cause or an effect of the depressive state. Although health care professionals continue to question the role of stressors and coping skills in the pathogenesis of disease states, we must resist the temptation to suggest that any disease is due to excessive stress or poor coping skills.

IN SUMMARY

Stress in itself is neither negative nor deleterious to health. The stress response is designed to be time limited and protective, but in situations of prolonged activation of the response because of overwhelming or chronic stressors, it could be damaging to health. PTSD is an example of chronic activation of the stress response as a result of experiencing a severe trauma. In this disorder, memory of the traumatic event seems to be enhanced. Flashbacks of the event are accompanied by intense activation of the neuroendocrine system.
Treatment of stress should be aimed at helping people avoid coping behaviors that can adversely affect their health and providing them with other ways to reduce stress. Nonpharmacologic methods used in the treatment of stress include relaxation techniques, guided imagery, music therapy, massage techniques, and biofeedback.

Research in stress has focused on personal reports of the stress situation and the physiologic responses to stress. A number of interview guides and written instruments are available for measuring the personal responses to acute and chronic stressors. Methods used for studying the physiologic manifestations of the stress response include electrocardiographic recording of heart rate, blood pressure measurement, electrodermal measurement of skin resistance associated with sweating, and biochemical analyses of hormone levels.

### Review Exercises

1. A 21-year-old college student notices that she frequently develops “cold sores” during the stressful final exam week.
   - **A.** What is the association between stress and the immune system?
   - **B.** One of her classmates suggests that she listen to music or try relaxation exercises as a means of relieving stress. Explain how these interventions might work in relieving stress.

2. A 75-year-old woman with congestive heart failure complains that her condition gets worse when she worries and is under stress.
   - **A.** Relate the effects stress has on the neuroendocrine control of cardiovascular function and its possible relationship to a worsening of the woman’s congestive heart failure.
   - **B.** She tells you that she dealt with much worse stresses when she was younger and never had any problems. How would you explain this?

3. A 30-year-old woman who was rescued from a collapsed building has been having nightmares recalling the event, excessive anxiety, and loss of appetite and is afraid to leave her home for fear something will happen.
   - **A.** Given her history and symptoms, what is the likely diagnosis?
   - **B.** How might she be treated?

Body temperature, at any given point in time, represents a balance between heat gain and heat loss. Body heat is generated in the core tissues of the body, transferred to the skin surface by the blood, and released into the environment surrounding the body. Body temperature rises in fever because of cytokine- and toll-like receptor-mediated changes in the set point of the temperature-regulating center in the hypothalamus. Body temperature rises in hyperthermia because of excessive heat production, inadequate heat dissipation, or a failure of thermoregulatory mechanisms. Body temperature falls during hypothermia due to exposure to cold. This chapter is organized into three sections: body temperature regulation, increased body temperature (fever and hyperthermia), and decreased body temperature (hypothermia).

Most biochemical processes in the body are affected by changes in temperature. Metabolic processes speed up or slow down depending on whether body temperature is rising or falling. Core body temperature (i.e., intracranial, intrathoracic, and intraabdominal) normally is maintained within a range of 36.0°C to 37.5°C (97.0°F to 99.5°F). Within this range, there are individual differences. For example, core temperature of most females increases approximately 0.5°C to 1.0°C during postovulation time of their menstrual cycle.
There are also diurnal variations. Internal core temperatures reach their highest point in late afternoon and evening and their lowest point in the early morning hours (Fig. 10.1). In fact, the core body temperature is generally lowest between 3:00 and 6:00 AM and highest during the late afternoon, 3:00 to 6:00 PM.\(^1\)

Body temperature reflects the difference between heat production and heat loss and varies with exercise and extremes of environmental temperature. For instance, exercise can increase metabolic heat production 10-fold.\(^1\) Thankfully, thermoregulatory responses such as sweating simultaneously increase heat loss, and thus keep body temperature from rising dangerously high. Shivering, on the other hand, increases metabolic heat production. This thermoregulatory response can offset the increased heat loss resulting from cold ambient conditions. Properly protected and hydrated, the body can function in environmental conditions that range from \(-50^\circ\text{C}\) (\(-58^\circ\text{F}\)) to \(+50^\circ\text{C}\) (122° F). The failure to adequately manage heat production and/or loss results in devastating consequences. For instance, ice crystals can form in tissues exposed to very cold and damp ambient temperatures. At the other extreme, very high temperatures (\(+45^\circ\text{C}\), 113° F) cause proteins to coagulate and/or aggregate. As will be discussed later in this chapter, much smaller, systemic changes in body temperature can be equally devastating, leading to tissue damage, organ failure, coma, and even death.\(^2\)

**KEY POINTS**

**THERMOREGULATION**

- Core body temperature is a reflection of the balance between heat gain and heat loss by the body. Metabolic processes produce heat, which must be dissipated.
- The hypothalamus is the thermal control center for the body, receives information from peripheral and central thermoreceptors, and compares that information with its temperature set point.
- An increase in core temperature is effected by vasoconstriction and shivering, a decrease in temperature by vasodilation and sweating.

Most of the body’s heat is produced by the deeper core tissues (i.e., muscles and viscera), which are insulated from the environment and protected against heat loss by an outer shell of subcutaneous tissues and skin (Fig. 10.2). The thickness of the shell depends on blood flow. In a warm environment, blood flow is increased and the thickness of the outer shell is decreased, allowing for greater dissipation of heat. In a cold environment, the vessels supplying blood flow to the skin and underlying tissues, including those of the limbs and more superficial muscles of the neck and trunk, constrict. This increases the thickness of the shell and helps to minimize the loss of core heat for the body. The subcutaneous fat layer contributes to the insulation value of the outer shell because of its thickness and because it conducts heat only about one third as effectively as other tissues.

Temperatures differ in various parts of the body, with core temperatures being higher than those at the skin surface. In general, the rectal temperature is used as a measure of core temperature and is considered the most accurate parameter.\(^3\) Rectal temperatures usually range from 37.3°C (99.1°F) to 37.6°C (99.6°F). Core temperatures may also be obtained from the esophagus using a flexible thermometer, from a pulmonary artery catheter that is used for thermodilution measurement of cardiac output, or from a urinary catheter with a thermosensor that measures the temperature of urine in the bladder. Because of location, pulmonary artery and esophageal temperatures closely reflect the temperatures of the heart and thoracic organs. The pulmonary artery catheter is the preferred measurement when body temperatures are changing rapidly.
and need to be followed reliably on an acutely ill person in an intensive care setting.

The oral temperature, taken sublingually, is usually 0.2°C (0.36°F) to 0.51°C (0.9°F) lower than the rectal temperature. However, it usually follows changes in core temperature closely. The axillary temperature also can be used as an estimate of core temperature. However, the parts of the axillary fossa must be pressed closely together for an extended period (5 to 10 minutes for a glass thermometer) because this method requires considerable heat to accumulate before the final temperature is reached.

Ear-based thermometry uses an infrared sensor to measure the flow of heat from the tympanic membrane and ear canal. It is popular in all health care settings because of its ease and speed of measurement, acceptability to all people, and cost savings in the personnel time that is required to take a temperature. However, there is continuing debate regarding the accuracy of this method. There is evidence to suggest that ear thermometry can predict rectal temperatures in normothermic and febrile older adults. In addition, studies with children demonstrate little evidence that the child’s age and gender and the environmental temperature or humidity impacted the reliability of the tympanic temperature.

Pacifier thermometers and skin temperature strips for children have also raised concerns about accuracy and are best used to monitor trends as opposed to absolute measurements.

Core body and skin temperatures are sensed and integrated by thermoregulatory regions in the hypothalamus (particularly, the preoptic–anterior hypothalamic area) and other brain structures (i.e., thalamus and cerebral cortex). Temperature-sensitive ion channels, identified as a subset of the transient receptor potential family (thermoTRPs), present in peripheral and central sensory neurons are activated by innocuous (warm and cool) and noxious (hot and cold) stimuli. Peripheral signals regarding temperature are initiated by changes in local membrane potentials that are transmitted to the brain through dorsal root ganglia. The set point of the hypothalamic thermoregulatory center is set so that the temperature of the body core is regulated within the normal range of 36.0°C (96.8°F) to 37.5°C (99.5°F). When body temperature begins to rise above the set point, the hypothalamus signals the central and peripheral nervous systems to initiate heat-dissipating behaviors. Likewise, when the temperature falls below the set point, signals from the hypothalamus elicit physiologic behaviors that increase heat conservation and production. Core temperatures above 41°C (105.8°F) or below 34°C (93.2°F) usually mean that the body’s ability to thermoregulate has been impaired. Body responses that produce, conserve, and dissipate heat are described in Table 10.1.

Spinal cord injuries that transect the cord at T6 or above can seriously impair temperature regulation because the thermoregulatory centers in the hypothalamus can no longer control skin blood flow and sweating.

In addition to reflexive and automatic thermoregulatory mechanisms, humans engage in voluntary behaviors to help regulate body temperature based on their conscious

sensation of being too hot or too cold. These behaviors include the selection of proper clothing and regulation of environmental temperature through heating systems and air conditioning. Body positions that hold the extremities close to the body prevent heat loss and are commonly assumed in cold weather.

**Mechanisms of Heat Production**

Metabolism is the body’s main source of heat production or thermogenesis. Many factors impact the metabolic rate, including:

- Metabolic rate of each cell
- Any factor that may increase the basal metabolic rate (BMR), such as that caused by muscle activity
- Extra metabolism caused by hormones, such as thyroxine, growth hormone, or testosterone
- Any extra metabolism caused by the sympathetic nervous system stimulation on cells
- Extra metabolism caused by increased cellular chemical activity
- Thermogenic effect of food digestion, absorption, or storage

There is a 0.55°C (1°F) increase in body temperature for every 7% increase in metabolism. The sympathetic neurotransmitters, epinephrine and norepinephrine, which are released when an increase in body temperature is needed, act at the cellular level to shift body metabolism to heat production rather than energy generation. This may be one of the reasons fever tends to produce feelings of weakness and fatigue. Thyroid hormone increases cellular metabolism, but this response usually requires several weeks to reach maximal effectiveness.

Fine involuntary actions such as shivering and chattering of the teeth can produce a three- to fivefold increase in body temperature. Shivering is initiated by impulses from the hypothalamus. Although shivering is an attempt to decrease the body temperature, it actually increases it and increases the use of oxygen by approximately 40%.

The first muscle change that occurs with shivering is a general increase in muscle tone, followed by an oscillating rhythmic tremor involving the spinal-level reflex that controls muscle tone. Physical exertion increases body temperature. Muscles convert most of the energy in the fuels they consume into heat rather than mechanical work. With strenuous exercise, more than three fourths of the increased metabolism resulting from muscle activity appears as heat within the body, and the remainder appears as mechanical work.

**Mechanisms of Heat Loss**

Most of the body’s heat losses occur at the skin surface as heat from the blood moves to the skin and from there into the surrounding environment. There are numerous arteriovenous (AV) anastomoses under the skin surface that allow blood to move directly from the arterial to the venous system. These AV anastomoses are much like the radiators in a heating system. When the shunts are open, body heat is freely dissipated to the skin and surrounding environment; when the shunts are closed, heat is retained in the body. The blood flow in the AV anastomoses is controlled almost exclusively by the sympathetic nervous system in response to changes in core temperature and environmental temperature. Contraction of the pilomotor muscles of the skin, which raises skin hairs and produces goose bumps, also aids in heat conservation by reducing the surface area available for heat loss.

Heat is lost from the body through radiation, conduction, and convection from the skin surface; through the evaporation of sweat and insensible perspiration; through the exhalation of air that has been warmed and humidified; and through heat lost in urine and feces. Of these mechanisms, only heat losses that occur at the skin surface are directly under hypothalamic control.

**Conduction**

Conduction is the direct transfer of heat from one molecule to another. Blood carries, or conducts, heat from the inner core of the body to the skin surface. Normally only a small amount of body heat is lost through conduction to a cooler surface. Cooling blankets or mattresses that are used for reducing fever rely on conduction of heat from the skin to the cool surface of the mattress. Heat also can be conducted in the opposite direction—from the external environment to the body surface. For instance, body temperature may rise slightly after a hot bath.

Water has a specific heat several times greater than air, so water absorbs far greater amounts of heat than air does. The loss of body heat can be excessive and life threatening in situations of cold water immersion or cold exposure in damp or wet clothing.

The conduction of heat to the body’s surface is influenced by blood volume. In hot weather, the body compensates by increasing blood volume as a means of dissipating heat. A mild swelling of the ankles during hot weather provides evidence of blood volume expansion. Exposure to cold produces a cold diuresis and a reduction in blood volume as a means of controlling the transfer of heat to the body’s surface.

**Convection**

Convection refers to heat transfer through the circulation of air currents. Normally, a layer of warm air tends to remain near the body’s surface. Convection causes continual removal of the warm layer and replacement with air from the surrounding environment. The wind-chill factor that often is included in the weather report combines the effect of convection due to wind with the still-air temperature.
Evaporation

Evaporation involves the use of body heat to convert water on the skin to water vapor. Water that diffuses through the skin independent of sweating is called insensible perspiration. Insensible perspiration losses are greatest in a dry environment. Sweating occurs through the sweat glands and is controlled by the sympathetic nervous system. Sweating is mediated by acetylcholine. This is unlike other sympathetically mediated functions in which the catecholamines serve as neuromediators. The impact of this is that anticholinergic drugs, such as atropine, can interfere with heat loss by interrupting sweating.

Evaporative heat losses involve insensible perspiration and sweating, with 0.58 cal being lost for each gram of water that is evaporated. As long as body temperature is greater than the atmospheric temperature, heat is lost through radiation. However, when the temperature of the surrounding environment becomes greater than skin temperature, evaporation is the only way the body can rid itself of heat. Any condition that prevents evaporative heat losses causes the body temperature to rise.

IN SUMMARY

Core body temperature is normally maintained within a range of 36.0°C to 37.5°C (97.0°F to 99.5°F). Core body and skin temperatures are sensed and integrated by thermoregulatory regions in the hypothalamus and other brain structures that function to modify heat production and heat loss as a means of regulating body temperature. Metabolic processes that occur within deeper core structures (i.e., muscles and viscera) of the body produce most of the body’s heat. The sympathetic neurotransmitters (epinephrine and norepinephrine) and thyroid hormone act at the cellular level to shift body metabolism to heat production, whereas shivering and chattering of the teeth use the heat liberated from involuntary muscle movements to increase body temperature. Most of the body’s heat losses occur at the skin surface as heat from the blood moves through the skin and from there into the surrounding environment. Heat is lost from the skin through radiation, conduction, convection, and evaporation of perspiration and sweat. Contraction of the pilomotor muscles of the skin aids in heat conservation by reducing the surface area available for heat loss.

INCREASED BODY TEMPERATURE

After completing this section of the chapter, you should be able to meet the following objectives:

- Characterize the physiology of fever.
- Differentiate between the physiologic mechanisms involved in fever and hyperthermia.
- Compare the mechanisms of malignant hyperthermia and neuroleptic malignant syndrome.

Both fever and hyperthermia describe conditions in which body temperature is higher than the normal range. Fever is due to an upward displacement of the thermostatic set point of the thermoregulatory center in the hypothalamus. This is in contrast to hyperthermia, in which the set point is unchanged, but the mechanisms that control body temperature are ineffective in maintaining body temperature within a normal range during situations when heat production outpaces the ability of the body to dissipate that heat.

Fever

Fever, or pyrexia, describes an elevation in body temperature that is caused by an upward displacement of the thermostatic set point of the hypothalamic thermoregulatory center. Temperature is one of the most frequent physiologic responses to be monitored during illness.

FEVER

- Fever represents an increase in body temperature that results from a cytokine-induced increase in the set point of the thermostatic center in the hypothalamus.
- Fever is a nonspecific response that is mediated by endogenous pyrogens released from host cells in response to infectious or noninfectious disorders.

Mechanisms

Many proteins, breakdown products of proteins, and certain other substances released from bacterial cell membranes can cause a change in the set point to rise. Fever is resolved when the condition that caused the increase in the set point is removed. Fevers that are regulated by the hypothalamus usually do not rise above 41°C (105.8°F), suggesting a built-in thermostatic safety mechanism. Temperatures above that level are usually the result of superimposed activity, such as convulsions, hyperthermic states, or direct impairment of the temperature control center.

Pyrogens are exogenous or endogenous substances that produce fever. Exogenous pyrogens are derived from outside the body and include such substances as bacterial products, bacterial toxins, or whole microorganisms. Exogenous pyrogens induce host cells to produce fever-producing mediators called endogenous pyrogens. When bacteria or breakdown products of bacteria are present in blood or tissues, phagocytic cells of the immune system engulf them. These phagocytic cells digest the bacterial products and then release pyrogenic cytokines, principally interleukin-1 (IL-1), interleukin-6 (IL-6), and tumor necrosis factor-α (TNF-α), into the bloodstream for transport to the hypothalamus, where they exert their action. These cytokines induce prostaglandin E₂ (PGE₂), which is a metabolite of...
Arachidonic acid (an intramembrane fatty acid). It is hypothesized that when interleukin (IL-1B) interacts with the endothelial cells of the blood–brain barrier in the capillaries of the organum vasculosum laminae terminalis (OVLT), which is in the third ventricle above the optic chiasm, PGE₂ is released into the hypothalamus.¹

At this point, PGE₂ binds to receptors in the hypothalamus to induce increases in the thermoregulatory set point through the second messenger cyclic adenosine monophosphate (cAMP). In response to the increase in its thermoregulatory set point, the hypothalamus initiates shivering and vasoconstriction that raise the body’s core temperature to the new set point, and fever is established.

Although the central role of PGE₂ in raising the set point of the hypothalamic thermoregulatory center and producing fever is not questioned, research suggests that the febrile response to invading gram-negative bacteria and their products (mainly endotoxin lipopolysaccharides) is mediated by PGE₂.²

In addition to their fever-producing actions, the endogenous pyrogens mediate a number of other responses. For example, IL-1 and TNF-α are inflammatory mediators that produce other signs of inflammation such as leukocytosis, anorexia, and malaise. Many noninfectious disorders, such as myocardial infarction, pulmonary emboli, and neoplasms, produce fever. In these conditions, the injured or abnormal cells incite the production of endogenous pyrogens. For example, trauma and surgery can be associated with up to 3 days of fever. Some malignant cells, such as those of leukemia and Hodgkin disease, secrete chemical mediators that function as endogenous pyrogens.

A fever that has its origin in the central nervous system is sometimes referred to as a neurogenic fever. It usually is caused by damage to the hypothalamus due to central nervous system trauma, intracerebral bleeding, or an increase in intracranial pressure. Neurogenic fever is characterized by a high temperature that is resistant to antipyretic therapy and is not associated with sweating.

### Purpose

The purpose of fever is not completely understood. However, from a purely practical standpoint, fever is a valuable index to health status. For many, fever signals the presence of an infection and may legitimate the need for medical treatment. There is little research to support the belief that fever is harmful unless the temperature rises above 40°C (104°F). However, animal studies have demonstrated a clear survival advantage in infected members with fever compared with animals that were unable to produce a fever. It has also been shown that small elevations in temperature such as those that occur with fever enhance immune function by T lymphocyte proliferation.³ Many of the microbial agents that cause infection grow best at normal body temperatures, and their growth is inhibited by temperatures in the fever range.

Yet, fever is negative in many situations such as in older adults who have cardiac or pulmonary disease because it causes more of a demand for oxygen. For every elevated 1°C of temperature, the BMR increases by 7% and causes increased work of the heart. Fever can also produce confusion, tachycardia, and tachypnea. Cell damage can occur when temperatures are elevated greater than 42.2°C (108°F), and this can ultimately cause life-threatening acidosis, hypoxia, and hyperkalemia.⁴

### Patterns

The patterns of temperature change in people with fever vary. Additionally, the average diurnal variation in temperature yields a peak rise in the late afternoon or early evening.² These patterns can be described as intermittent, remittent, sustained, or relapsing (Fig. 10.3). An intermittent fever is one in which temperature returns to normal at least once every 24 hours. In a remittent fever, the temperature does not return to normal and varies a few degrees in either direction. In a sustained or continuous fever, the temperature remains above normal with minimal variations (usually <0.5°C or 1°F). A recurrent or relapsing fever is one in which there is one or more episodes of fever, each as long as several days, with one or more days of normal temperature between episodes.

Critical to the analysis of a fever pattern is the relation of heart rate to the level of temperature elevation. Most people respond to an increase in temperature with an appropriate increase in heart rate. The observation that a rise in temperature is not accompanied by the anticipated change in heart rate can provide useful information about the cause of the fever. For example, a heart rate that is slower than would be anticipated can occur with Legionnaire disease and drug fever, and a heart rate that is more rapid than anticipated can be symptomatic of hyperthyroidism and pulmonary emboli.

### Clinical Manifestations

The physiologic behaviors that occur during the development of fever can be divided into four successive stages (Fig. 10.4):

1. A prodrome
2. A chill, during which the temperature rises
3. A flush
4. A defervescence

During the first or prodromal period, there are nonspecific complaints such as mild headache and fatigue, general malaise, and fleeting aches and pains. During the second stage or chill, there is the uncomfortable sensation of being chilled and the onset of generalized shaking (rigors), although the temperature is rising. Vasoconstriction and piloerection usually precede the onset of shivering. At this point, the skin is pale and covered with goose flesh. There is a feeling of being cold and an urge to put on more clothing or covering and to curl up in a position that conserves body heat. When the shivering has caused the body temperature to reach the new set point of the temperature control center, the shivering ceases, and a sensation of warmth develops. At this point, the third stage or flush begins, during which cutaneous vasodilation occurs and the skin becomes warm and flushed. The fourth, or defervescence,
stage of the febrile response is marked by the initiation of sweating. Not all people proceed through the four stages of fever development. Sweating may be absent, and fever may develop gradually with no indication of a chill or shivering.

Common clinical manifestations of fever are anorexia, myalgia, arthralgia, and fatigue. These discomforts are worse when the temperature rises rapidly or exceeds 39.5°C (103.1°F). Respiration is increased, and the heart rate usually is elevated. Dehydration occurs because of sweating and the increased vapor losses due to the rapid respiratory rate. Many of the manifestations of fever are related to the increases in the metabolic rate, increases in oxygen demands, and use of body proteins as an energy source. With prolonged fever, there is an increased breakdown of endogenous fat stores. If fat breakdown is rapid, metabolic acidosis may result.

Headache is a common accompaniment of fever and is thought to result from the vasodilation of cerebral vessels occurring with fever. Delirium is possible when the temperature exceeds 40°C (104°F). However, in older adults, confusion and delirium may follow only moderate elevations in

![Schematic representation of fever patterns](image-url)
temperature. Owing to increasingly poor oxygen uptake by the aging lung, pulmonary function may prove to be a limiting factor in the hypermetabolism that accompanies fever in older persons. Confusion, incoordination, and agitation commonly reflect cerebral hypoxemia. Herpetic lesions, or fever blisters, that develop in some people during fever are caused by a separate infection by the type 1 herpes simplex virus that established latency in the regional ganglia and is reactivated by a rise in body temperature.

**Diagnosis**

Most febrile illnesses are due to common infections and are relatively easy to diagnose. In certain instances, however, it is difficult to establish the cause of a fever. A prolonged fever for which the cause is difficult to ascertain is often referred to as fever of unknown origin (FUO) or unexplained persistent fever. FUO is defined as a temperature elevation of 38.3°C (101°F) or higher that is present for 3 weeks or longer and includes 1 week of comprehensive diagnostic testing that does not identify a diagnosis. Among the causes of FUO are malignancies (i.e., lymphomas, metastases to the liver and central nervous system); infections such as human immunodeficiency virus, tuberculosis, or abscessed infections; and drug fever. Malignancies, particularly non-Hodgkin lymphoma, are important causes of FUO in the elderly. Cirrhosis of the liver is another cause of FUO.

Recurrent or periodic fevers may occur in predictable intervals or without any discernible time pattern. They may be associated with no discernible cause, or they can be the presenting symptom of several serious illnesses, often preceding the other symptoms of those diseases by weeks or months. Conditions in which recurrent fevers occur but do not follow a strictly periodic pattern include genetic disorders such as familial Mediterranean fever. Familial Mediterranean fever, an autosomal recessive disease, is characterized by an early age of onset (<20 years) of acute episodic bouts of peritonitis and high fever with an average duration of less than 2 days. In some cases pleuritis, pericarditis, and arthritis are present. The primary chronic complication is the presence of serum antibodies that can result in kidney or heart failure. Other conditions that present with recurrent fevers occurring at irregular intervals include repeated viral or bacterial infections, parasitic and fungal infections, and some inflammatory conditions, such as lupus erythematosus or Crohn disease. The clinical challenge is in the differential diagnosis of periodic or recurrent fever. The initial workup usually requires a thorough history and physical examination designed to rule out the more serious medical conditions that present initially with fever.

**Treatment**

The methods of fever treatment focus on modifications of the external environment intended to increase heat transfer from the internal to the external environment, support of the hypermetabolic state that accompanies fever, protection of vulnerable body organs and systems, and treatment of the infection or condition causing the fever. Because fever is a disease symptom, its manifestation suggests the need for diagnosis and treatment of the primary cause.

Modification of the environment ensures that the environmental temperature facilitates heat transfer away from the body. Sponge baths with cool water or an alcohol solution can be used to increase evaporative heat losses, but caution is necessary so the person is not cooled too quickly. It is better to bring the person to a health care practice to obtain advice on whether the person may need intravenous lines for hydration and other medical attention. More profound cooling can be accomplished through the use of forced air blankets or a cooling mattress, which facilitates the conduction of heat from the body into the coolant solution that circulates through the mattress. Care must be taken so that the cooling method does not produce vasoconstriction and shivering that decrease heat loss and increase heat production.

Adequate fluids and sufficient amounts of simple carbohydrates are needed to support the hypermetabolic state and prevent the tissue breakdown that is characteristic of fever. Additional replacement fluids are needed for sweating and to balance the insensible water losses from the lungs that accompany an increase in respiratory rate. Fluids also are needed to maintain an adequate vascular volume for heat transport to the skin surface.

Antipyretic drugs, such as aspirin, ibuprofen, and acetaminophen, often are used to alleviate the discomforts of fever and protect vulnerable organs, such as the brain, from extreme elevations in body temperature. It is thought that these drugs act by resetting the set point of the temperature-regulating center in the hypothalamus to a lower level, presumably by blocking the activity of cyclooxygenase, an enzyme that is required for the conversion of arachidonic acid to PGE2. However, evidence suggests that the routine administration of antipyretics does not decrease the duration of the fever or illness. Because of the risk of Reye syndrome, the Centers for Disease Control and Prevention, U.S. Food and Drug Administration, and American Academy of Pediatrics Committee on Infectious Diseases advise against the use of aspirin and other salicylates in children with influenza or chickenpox.

**Fever in Children**

Fever occurs frequently in infants and young children and is a common reason for visits to the emergency department. Infants and young children have decreased immunologic function and are more commonly infected with virulent organisms. Also, the mechanisms for controlling temperature are not as well developed in infants as they are in older children and adults. Even though infants with fever may not appear ill, this does not imply an absence of bacterial disease. In infants younger than 3 months, a mild elevation in temperature (i.e., rectal temperature of 38°C [100.4°F]) can indicate serious infection.

Although the differential diagnosis of fever is quite broad and includes both infectious and noninfectious causes, the majority of febrile children have an underlying infection. The most common causes are minor or more serious infections of the respiratory system, gastrointestinal tract,
urinary tract, or central nervous system. The epidemiology of serious bacterial disease has changed dramatically with the introduction of the *Haemophilus influenzae* and *Streptococcus pneumoniae* vaccines in developed countries. *H. influenzae* type b has been nearly eliminated, and the incidence of pneumococcal disease caused by vaccine and cross-reactive vaccine serotypes has declined substantially. Fever in infants and children can be classified as low risk or high risk, depending on the probability of the infection progressing to bacteremia or meningitis and signs of toxicity. Infants between the ages of 1 and 28 days with a fever should be considered to have a bacterial infection that can cause bactere mia or meningitis. Signs of toxicity include lethargy, poor feeding, hyperventilation, poor tissue oxygenation, and cyanosis. A white blood cell count with differential and blood cultures usually is taken in high-risk infants and children to determine the cause of fever. A chest radiograph should be obtained in febrile infants younger than 3 months of age with at least one sign of a respiratory illness (e.g., tachypnea, crackles, decreased breath sounds, wheezing, coughing). Febrile children who are younger than 1 year of age and girls between 1 and 2 years of age should be considered at risk for a urinary tract infection.10

The approach to treatment of the young child who has a fever without a known source varies depending on the age of the child. High-risk infants and infants who are younger than 28 days are often hospitalized for evaluation of their fever and treatment.10

### Fever in Older Adults

In the elderly, even slight elevations in temperature may indicate serious infection or disease, most often caused by bacteria. This is because the elderly often have a lower baseline temperature, and although they increase their temperature during an infection, it may fail to reach a level that is equated with significant fever.10.11 Normal body temperature and the circadian pattern of temperature variation often are altered in the elderly. Fever in the older adult does increase the older adult’s immunological response, but it is generally a much weaker response compared to younger people.12

It has been suggested that 20% to 30% of older adults with serious infections present with an absent or blunted febrile response.13 The probable mechanisms for the blunted fever response include a disturbance in sensing of temperature by the thermoregulatory center in the hypothalamus, alterations in release of endogenous pyrogens, and the failure to elicit responses such as vasconstriction of skin vessels, increased heat production, and shivering that increase body temperature during a febrile response.

Absence of fever may delay diagnosis and initiation of antimicrobial treatment. Therefore, it is important to perform a thorough history and physical examination focusing on other signs of infection and sepsis in older adults. Signs of infection in older adults when fever is absent include unexplained changes in functional capacity, worsening of mental status, weakness and fatigue, and weight loss.

Another factor that may delay recognition of fever in older adults is the method of temperature measurement. It has been suggested that rectal and tympanic membrane methods are more effective in detecting fever in the elderly. This is because conditions such as mouth breathing, tongue tremors, and agitation often make it difficult to obtain accurate oral temperatures in older adults.

### Hyperthermia

Hyperthermia describes an increase in body temperature that occurs without a change in the set point of the hypothalamic thermoregulatory center. It occurs when the thermoregulatory mechanisms are overwhelmed by heat production, excessive environmental heat, or impaired dissipation of heat.12 It includes (in order of increasing severity) heat cramps, heat exhaustion, and heatstroke. Malignant hyperthermia describes a rare genetic disorder of anesthetic-related hyperthermia. Hyperthermia also may occur as the result of a drug reaction.

A number of factors predispose to hyperthermia. If muscle exertion is continued for long periods in warm weather, as often happens with athletes, military recruits, and laborers, excessive heat loads are generated. Because adequate circulatory function is essential for heat dissipation, elderly people and those with cardiovascular disease are at increased risk for hyperthermia. Drugs that increase muscle tone and metabolism or reduce heat loss (e.g., diuretics, neuroleptics, drugs with anticholinergic action) can impair thermoregulation. Infants and small children who are left in a closed car for even short periods in hot weather are potential victims of hyperthermia.

The best approach to heat-related disorders is prevention, primarily by avoiding activity in hot environments, increasing fluid intake, and wearing climate- and activity-appropriate clothing. The ability to tolerate a hot environment depends on both temperature and humidity. A high relative humidity retards heat loss through sweating and evaporation and decreases the body’s cooling ability. The *heat index* is the temperature that the body senses when both the temperature and humidity are combined.

### KEY POINTS

**HYPERTERMIA**

- Hyperthermia is a pathologic increase in core body temperature without a change in the hypothalamic set point. The thermoregulatory center is overwhelmed by either excess heat production, impaired heat loss, or excessive environmental heat.
- Malignant hyperthermia is an autosomal dominant disorder in which an abnormal release of intracellular stores of calcium causes uncontrolled skeletal muscle contractions, resulting in a rapid increase in core body temperature. This usually is in response to an anesthetic.
Heat Cramps
Heat cramps are slow, painful, skeletal muscle cramps and spasms, usually occurring in the muscles that are most heavily used and lasting for 1 to 3 minutes. Cramping results from salt depletion that occurs when fluid losses from heavy sweating are replaced by water alone. The muscles are tender, and the skin usually is moist. Body temperature may be normal or slightly elevated. There almost always is a history of vigorous activity preceding the onset of symptoms.

Heat Exhaustion
Heat exhaustion is related to a gradual loss of salt and water, usually after prolonged and heavy exertion in a hot environment. The symptoms include thirst, fatigue, nausea, oliguria, giddiness, and finally delirium. Gastrointestinal flulike symptoms are common. Hyperventilation in association with heat exhaustion may contribute to heat cramps and tetany by causing respiratory alkalosis. The skin is moist, the rectal temperature usually is higher than 37.8°C (100°F) but below 40°C (104°F), and the heart rate is elevated. Signs of heat cramps may accompany heat exhaustion.

Heatstroke
Heatstroke is a severe, life-threatening failure of thermoregulatory mechanisms resulting in an excessive increase in body temperature—a core temperature greater than 40°C (104°F); a hot, dry skin; absence of sweating; and possible central nervous system abnormalities such as delirium, convulsions, and loss of consciousness.14 There are approximately 240 deaths/year from exercise-related heatstroke in the United States alone.15 The risk of developing heatstroke in response to heat stress is increased in conditions (i.e., alcoholism, obesity, diabetes mellitus, and chronic cardiac, renal, or mental disease) and with drugs (i.e., alcohol, anticholinergics, beta blockers, or tricyclic antidepressants) that impair vasodilation and sweating.14

The pathophysiology of heatstroke is thought to result from the direct effect of heat on body cells and the release of cytokines (e.g., interleukins, TNF-α, and interferon) from heat-stressed endothelial cells, leukocytes, and epithelial cells that protect against tissue injury. The net result is a combination of local and systemic inflammatory responses that may result in acute respiratory distress syndrome, acute renal failure, disseminated intravascular coagulation, and multiorgan disorders.

The symptoms of heatstroke include tachycardia, hyperventilation, dizziness, weakness, emotional lability, nausea and vomiting, confusion, delirium, blurred vision, convulsions, collapse, and coma. The skin is hot and usually dry, and the pulse is typically strong initially. The blood pressure may be elevated at first, but hypotension develops as the condition progresses. As vascular collapse occurs, the skin becomes cool. Associated abnormalities include electrocardiographic changes consistent with heart damage, blood coagulation disorders, potassium and sodium depletion, and signs of liver damage.

Treatment consists of measures to support the function of vital organs while instituting cooling procedures aimed at producing a rapid reduction in core temperature. Care must be taken that the cooling methods used do not produce vasoconstriction or shivering and thereby decrease the cooling rate or induce heat production.

Drug Fever
Drug fever has been defined as fever coinciding with the administration of a drug and disappearing after the drug has been discontinued.2 Drugs can induce fever by several mechanisms. They can interfere with heat dissipation, they can alter temperature regulation by the hypothalamic centers, they can act as direct pyrogens, they can injure tissues directly, or they can induce an immune response.

Exogenous thyroid hormone increases the metabolic rate and can increase heat production and body temperature. Research demonstrates that propylthiouracil (PTU) has several side effects including fever and that use of PTU can induce fever and cause interstitial pneumonia.16 Peripheral heat dissipation can be impaired by atropine and anticholinergic drugs, antihistamines, phenothiazine antipsychotic drugs, and tricyclic antidepressants, which decrease sweating, or by amphetamines (especially ecstasy), cocaine, and sympathomimetic drugs, which produce peripheral vasoconstriction.2 Intravenously administered drugs can lead to infusion-related phlebitis with production of cellular pyrogens that produce fever. Treatment with antinecancer drugs can cause the release of endogenous pyrogn from the cancer cells that are destroyed. Overdoses of serotonin reuptake inhibitors or use in people taking monoamine oxidase (MOA) inhibitors can cause agitation, hyperactivity, and hyperthermia (serotonin syndrome).2

The most common cause of drug fever is a hypersensitivity reaction. Hypersensitivity drug fevers develop after several weeks of exposure to the drug, cannot be explained in terms of the drug’s pharmacologic action, are not related to drug dose, disappear when the drug is stopped, and reappear when the drug is readministered. The fever pattern is typically spiking in nature and exhibits a normal diurnal rhythm. Persons with drug fevers often experience other signs of hypersensitivity reactions, such as arthralgias, urticaria, myalgias, gastrointestinal discomfort, and rashes.

Temperatures of 38.9°C to 40.0°C (101.8°F to 104.0°F) are common in drug fever. The person may be unaware of the fever and appear to be well for the degree of fever that is present. The absence of an appropriate increase in heart rate for the degree of temperature elevation is an important clue to the diagnosis of drug fever. A fever often precedes other, more serious effects of a drug reaction. For this reason, the early recognition of drug fever is important. Drug fever should be suspected whenever the temperature elevation is unexpected and occurs despite improvement in the condition for which the drug was prescribed.

Malignant Hyperthermia
Malignant hyperthermia is an autosomal dominant metabolic disorder in which heat generated by uncontrolled skeletal muscle contraction can produce severe and potentially fatal hyperthermia.2 Generally, the mutation involves...
The neuroleptic malignant syndrome is associated with neuroleptic (psychotropic) medications and may occur in as many as 0.02% to 3.23% of people taking such drugs. Most of these drugs block dopamine receptors in the basal ganglia and hypothalamus. Hyperthermia is thought to result from alterations in the function of the hypothalamic thermoregulatory center. Because many of the neuroleptic drugs produce an increase in muscle contraction similar to that of malignant hyperthermia, it has been suggested that the disorder may be caused by a spectrum of inherited defects in genes that are responsible for a variety of calcium regulatory mechanisms in sympathetic neurons (e.g., dopaminergic neurons). The syndrome usually has an explosive onset and is characterized by hyperthermia, muscle rigidity, alterations in consciousness, and autonomic nervous system dysfunction. The hyperthermia is accompanied by tachycardia, cardiac dysrhythmias, labile blood pressure dyspnea, and tachypnea.

Treatment for neuroleptic malignant syndrome includes the immediate discontinuance of the neuroleptic drug, measures to decrease body temperature, and treatment of dysrhythmias and other complications of the disorder. Bromocriptine (a dopamine agonist) and dantrolene (a muscle relaxant) may be used as part of the treatment regimen.

**IN SUMMARY**

Fever and hyperthermia refer to an increase in body temperature outside the normal range. True fever is a disorder of thermoregulation in which there is an upward displacement of the set point for temperature control. In hyperthermia, the set point is unchanged, but the challenge to temperature regulation exceeds the thermoregulatory center’s ability to control body temperature. Fever can be caused by a number of factors, including microorganisms, trauma, and drugs or chemicals, all of which incite the release of endogenous pyrogens. The reactions that occur during fever consist of four stages: a prodrome, a chill, a flush, and a defervescence. A fever can follow an intermittent, remittent, sustained, or recurrent pattern. The manifestations of fever are largely related to dehydration and an increased metabolic rate. Even a low-grade fever in high-risk infants or in older adults can indicate serious infection.

The treatment of fever focuses on modifying the external environment as a means of increasing heat transfer to the external environment, supporting the hypermetabolic state that accompanies fever, protecting vulnerable body tissues, and treating the infection or condition causing the fever.

Hyperthermia, which varies in severity based on the degree of core temperature elevation and the severity of cardiovascular and nervous system involvement, includes heat cramps, heat exhaustion, and heatstroke. Among the factors that contribute to the development of hyperthermia are prolonged muscular exertion in a hot environment, disorders that compromise heat dissipation, and hypersensitivity drug reactions. Malignant hyperthermia is an autosomal dominant disorder that can produce a severe and potentially fatal increase in body temperature. The condition commonly is triggered by general anesthetic agents and muscle relaxants used during surgery. The neuroleptic malignant syndrome is associated with neuroleptic drug therapy and is thought to result from alterations in the function of the thermoregulatory center or from uncontrolled muscle contraction.

**DECREASED BODY TEMPERATURE**

After completing this section of the chapter, you should be able to meet the following objectives:

- Define hypothermia.
- Compare the manifestations of mild, moderate, and severe hypothermia and relate them to changes in physiologic functioning that occur with decreased body temperature.
- Describe the causes of heat loss and hypothermia in the newborn infant and in the person undergoing surgery.
Hypothermia

Hypothermia is defined as a core temperature (i.e., rectal, esophageal, or tympanic) less than 35°C (95°F). Accidental hypothermia may be defined as a spontaneous decrease in core temperature, usually in a cold environment and associated with an acute problem but without a primary disorder of the temperature-regulating center. In children, the rapid cooling process, in addition to the diving reflex that triggers apnea and circulatory shunting to establish a heart–brain circulation, may account for the surprisingly high survival rate after submersion. The diving reflex is greatly diminished in adults.

Systemic hypothermia may result from exposure to prolonged cold (atmospheric or submersion). The condition may develop in otherwise healthy people in the course of accidental exposure. Because water conducts heat more readily than air, body temperature drops rapidly when the body is submerged in cold water or when clothing becomes wet. In people with altered homeostasis due to debility or disease, hypothermia may follow exposure to relatively small decreases in atmospheric temperature.

Many underlying conditions can contribute to the development of hypothermia. Malnutrition decreases the fuel available for heat generation, and loss of body fat decreases tissue insulation. Alcohol and sedative drugs dull mental awareness to cold and impair judgment to seek shelter or put on additional clothing. Alcohol also inhibits shivering. People with cardiovascular disease, cerebrovascular disease, spinal cord injury, and hypothyroidism also are predisposed to hypothermia.

Neonatal Hypothermia

Infants are particularly at risk for hypothermia because of their high ratio of surface area to body mass. Relative to body weight, the body surface area of an infant is three times that of an adult, and in infants with low birth weight, the insulating layer of subcutaneous fat is thinner. The newborn infant is particularly at risk, but the premature newborn is at greatest risk for heat loss and hypothermia. Under the usual delivery room conditions (20°C to 25°C [68°F to 77°F]), an infant’s skin temperature falls approximately 0.3°C/minute and deep body temperature by approximately 0.1°C/minute. The heat loss occurs by convection to the cooler surrounding air, by conduction to cooler materials on which the infant is resting, by radiation to nearby cooler solid objects, and by evaporation from the moist skin. The unstable body temperature of a preterm infant can drop precipitously after delivery, and this hypothermia is associated with an increase in morbidity and mortality.

The newborn infant does have one important process to fight against hypothermia. This process is called nonshivering thermogenesis, and it occurs primarily in the liver, brown fat tissue, and brain. Brown fat differs from regular adipose tissue because it has a high number of mitochondria. Newborns have this brown fat tissue in their necks and upper back. The brown fat has an uncoupling protein called UCP1 (thermogenin), which allows oxidation of fatty acids to produce heat. The extreme cold temperature stimulates a release of epinephrine and TSH, which causes a release of T3 and T4. Epinephrine activates the 5′3′-monodeiodinase, which assists with the conversion of T4 to the more rapid-acting T3. The T3 acts in the brown fat to release the mitochondrial oxidation from phosphorylation. This, in turn, causes more heat production.

Perioperative Hypothermia

People who undergo surgical procedures are also at risk for hypothermia. It is especially important to prevent hypothermia in thin, debilitated, intoxicated, and older people undergoing surgery by using rewarming therapies and other nursing interventions such as decreased skin exposure and preoperative warming. Perioperative hypothermia is the result of a cold environment and impaired thermoregulatory mechanisms brought about by anesthetics and other drugs. It is important to realize that for each one degree temperature loss, there is a 7% decrease in metabolic demands by the body. Both general and regional anesthetic agents disrupt many of the body’s thermoregulatory mechanisms. General anesthetic agents lower the metabolic rate and decrease vasoconstriction and shivering thresholds. Postanesthetic shivering is a common complication of modern anesthesia. Apart from discomfort, postanesthesia shivering is associated with a number of potentially dangerous sequelae, including increased oxygen consumption and carbon dioxide production, increased cardiorespiratory effort, and effects of increased catecholamine (epinephrine and norepinephrine) release. These effects can pose a problem to recovery in vulnerable populations such as older adults and people with marginal cardiopulmonary reserves, impaired oxygen-carrying capacity (anemia), and other health problems.

A number of methods are used to prevent heat loss during surgery. Core temperature monitoring, accompanied by passive and active methods to maintain normal body temperature, should be part of routine inoperative monitoring. In many cases, some form of active rewarming is required. Preoperatively, patients are assessed carefully for any type of infection, if one is found, surgery will be postponed.

Clinical Manifestations

The signs and symptoms of hypothermia include poor coordination, stumbling, slurred speech, irrationality and poor judgment, amnesia, hallucinations, blueness and puffiness of the skin, dilation of the pupils, decreased respiratory rate, weak and irregular pulse, and stupor. With mild hypothermia, intense shivering generates heat and sympathetic nervous system activity is raised to resist lowering of temperature. Vasoconstriction can be profound, heart rate is accelerated, and stroke volume is increased. Blood pressure increases slightly, and hyperventilation is common. Exposure to cold augments urinary flow (i.e., cold diuresis) before there is any fall in temperature. Dehydration and increased hematocrit may develop within a few hours of even mild hypothermia, augmented by an extracellular-to-intracellular water shift.

With moderate hypothermia, shivering gradually decreases, and the muscles become rigid. Heart rate and stroke volume are reduced, and blood pressure falls, along with metabolic rate. Associated with this decrease in metabolic rate is a decrease in oxygen consumption and carbon dioxide production.
is roughly a 7% decrease in oxygen consumption for every 1°C (2°F) decrease in temperature. A decrease in carbon dioxide production leads to a decrease in respiratory rate. Respirations decrease as temperatures drop below 32.2°C (90°F). Decreases in mentation, the cough reflex, and respiratory tract secretions may lead to difficulty in clearing secretions and aspiration. In terms of cardiovascular function, a gradual decline in heart rate and cardiac output occurs as hypothermia progresses. Blood pressure initially rises and then gradually falls. There is increased risk of dysrhythmia developing, probably from myocardial hypoxia and autonomic nervous system imbalance. Ventricular fibrillation is a major cause of death in hypothermia.

Carbohydrate metabolism and insulin activity are decreased, resulting in a hyperglycemia that is proportional to the level of cooling. A cold-induced loss of cell membrane integrity allows intravascular fluids to move into the skin, giving the skin a puffy appearance. Acid–base disorders occur with increased frequency at temperatures below 25°C (77°F) unless adequate ventilation is maintained. Extracellular sodium and potassium concentrations decrease, and chloride levels increase. There is a temporary loss of plasma from the circulation along with sludging of red blood cells and increased blood viscosity as the result of trapping in the small vessels and skin.

**Diagnosis and Treatment**

Oral temperatures are markedly inaccurate during hypothermia because of severe vasoconstriction and sluggish blood flow. Electronic thermometers with flexible probes are available for measuring rectal, bladder, and esophageal temperatures. Most clinical thermometers measure temperature only in the range of 35°C to 42°C (95°F to 107.6°F); a special thermometer that registers as low as 25°C (77°F) or an electrical thermistor probe is needed for monitoring temperatures in people with hypothermia. Treatment of hypothermia consists of rewarming, support of vital functions, and the prevention and treatment of complications.

**Therapeutic Hypothermia**

Controlled hypothermia may be used after brain injury and during certain types of surgery to decrease inflammation and brain metabolism. This controlled therapeutic hypothermia has been found helpful for people who have had cardiac arrest due to ventricular fibrillation in terms of increasing the person’s neurological outcomes. Intraoperatively, especially with cardiothoracic surgery, patients are kept hypothermic between 82.4°F and 89.6°F to decrease metabolic demands and prevent ischemic injury. Myocardial ischemia is prevented by injecting cold cardioplegia solution at 39.2°F into the aortic root under pressure. This solution is heavily composed of potassium, which causes asystole and hypothermia to protect the myocardium during the surgery. Additionally, to maintain myocardial hypothermia, an iced normal saline slush is administered topically. There are, however, some potential complications to cold cardioplegia, such as ventricular dysrhythmias, decreased cerebral blood flow, and postoperative myocardial depression. Therefore, some surgeons use a normothermic blood cardioplegia. After the surgery is complete, warmed blood is perfused to patients who were hypothermic during surgery. It takes some time to rewarm the person back to 98.6°F core body temperature, and the rewarming has to be performed slowly. Attempts to prevent shivering and severe vasoconstriction are made. However, if there is a bleeding problem postoperatively, the person needs to have a restoration of body temperature as quickly and as safely as possible. Currently there is much controversy over using hypothermia for situations such as traumatic brain injury, cardiac arrest, spinal cord injury, stroke, increased intracranial pressure, hepatic encephalopathy, and spinal cord injury.

**IN SUMMARY**

Hypothermia is a potentially life-threatening disorder in which the body’s core temperature drops below 35°C (95°F). Accidental hypothermia can develop in otherwise healthy people in the course of accidental exposure and in older adults or disabled people with impaired perception of or response to cold. Alcoholism, cardiovascular disease, malnutrition, and hypothyroidism contribute to the risk of hypothermia. Hypothermia is also a common occurrence in newborn infants, particularly those born prematurely and in people undergoing an operation. The greatest effect of hypothermia is a decrease in the metabolic rate, leading to a decrease in carbon dioxide production and respiratory rate. Clinical manifestations of hypothermia include poor coordination, stumbling, slurred speech, irrationality, poor judgment, amnesia, hallucinations, blueness and puffiness of the skin, dilation of the pupils, decreased respiratory rate, weak and irregular pulse, stupor, and coma. Treatment of hypothermia includes passive or active rewarming, support of vital functions, and the prevention and treatment of complications.

**REVIEW EXERCISES**

1. A 3-year-old child is seen in a pediatric clinic with a temperature of 39°C (102.2°F). Her skin is warm and flushed, her pulse is 120 beats/minute, and her respirations are shallow and rapid at 32 breaths/minute. Her mother states that her daughter has complained of a sore throat and has refused to drink or take medications to bring her temperature down.

   **A.** Explain the physiologic mechanisms of fever generation.

   **B.** Are the warm and flushed skin, rapid heart rate, and increased respirations consistent with this level of fever?

   **C.** After receiving an appropriate dose of acetaminophen, the child begins to sweat, and the temperature drops to 37.2°C (98.9°F). Explain the physiologic mechanisms responsible for the drop in temperature.
2. A 25-year-old man was brought to the emergency department after having been found unconscious in a snow bank. The outdoor temperature at the time he was discovered was −23.3°C (−10°F). His car, which was stalled a short distance away, contained liquor bottles, suggesting that he had been drinking. His temperature on admission was 29.8°C (85.6°F). His heart rate was 40 beats/minute and his respirations 18 breaths/minute and shallow. His skin was cool, his muscles rigid, and his digits blue.

A. What factors might have contributed to this man’s state of hypothermia?
B. Is this man able to engage in physiologic behaviors to control loss of body heat
C. Given two methods that are available for taking this man’s temperature (oral or rectal), which would be more accurate? Explain.
D. What precautions should be considered when deciding on a method for rewarming this man?

References
Exercise, or physical activity, is a physiologic state, so common in its many forms that true physiologic rest is seldom achieved. Defined ultimately in terms of skeletal muscle contraction, exercise involves the coordinated responses of each body system to provide the energy needed for increased muscle activity. Fatigue represents the perceived lack of sufficient energy to engage fully in physical activities. Fatigue may be acute, as in that resulting from increased physical activity, or it may be chronic, as in the chronic fatigue syndrome (CFS). Conditions that restrict physical activity, such as bed rest and immobility, can impair a person’s exercise reserve and ability to perform work and other activities.

This chapter focuses on activity tolerance and exercise, activity intolerance and fatigue, and the physiologic and psychosocial responses to immobility and bed rest.
There is increasing interest in both the preventive and therapeutic effects of physical activity and exercise. A regular program of exercise is recommended as a means of maintaining weight control and cardiovascular fitness. Exercise partnered with diet control also is becoming recognized as an integral part of the treatment regimen for many diseases. It is recommended as a means of slowing, or even halting, the progression of atherosclerotic coronary heart disease (CHD); of lowering low-density lipoproteins (LDLs) and increasing high-density lipoproteins (HDLs) in persons with hyperlipidemia; of providing better regulation of blood glucose in people with diabetes; and of improving activity tolerance in people with cardiovascular and respiratory diseases. People who have metabolic syndrome, which includes abdominal obesity, hypertension, lidemia, and insulin resistance, can greatly impact their health with an improved diet and exercise program.2

Although there is a growing consensus regarding the importance of physical activity and exercise, there are questions regarding the type, intensity, frequency, and duration. A single episode of acute exercise may provoke responses quite different from the adaptations seen when exercise is experienced on a regular basis.

**KEY POINTS**

**ACTIVITY TOLERANCE**

- Activity is the process of purposeful energy expenditure. Exercise, a form of activity that results in overall conditioning of the body, can be aerobic or isometric.
- Exercise depends on the availability of energy substrates, cardiovascular fitness, muscle strength and flexibility, and motivation.

**Types of Exercise**

There are two main types of skeletal muscle exercise: aerobic and isometric. Another type—flexibility or stretching exercise—promotes flexibility and improved range of joint motion. Evidence supports the use of all three types in one’s exercise program.3

**Aerobic Exercise**

*Aerobic, or endurance, exercise* involves the body’s ability to improve its use of oxygen for energy during prolonged strenuous exercise. It involves rhythmic changes in muscle length (contraction and elongation) during activities such as walking, running, bicycling, or swimming.4 During aerobic exercise that uses large muscle groups (e.g., running), each person has a maximal oxygen uptake that cannot be exceeded, although it can be increased with appropriate training.4 Although aerobic exercise training results in muscles that use oxygen more efficiently such that the body can do more work with less cardiac and respiratory effort, it does not promote significant increase in muscle mass, even though the exercise may go on for hours.4 Evidence reveals multiple advantages for people who participate in sustained aerobic exercises, including oxidative stress reduction.5 However, studies do not show effective cognitive function improvement in people with neurological disorders after participating in aerobic exercises.6

Whatever type of exercise a person chooses, the American College of Sports Medicine (ACSM) recommends that adults strive for at least 20 to 60 minutes of moderate-intensity (55% to 65% of maximum heart rate) physical activity 3 to 5 days a week or 20 minutes or more of vigorous-intensity (70% to 85% of maximum heart rate) activity for 3 or more days a week.7 The Centers for Disease Control (2008) advocates that all adults should engage in daily moderate physical activity for approximately 60 minutes/day. The CDC further specified that some of this time should include muscle and bone strengthening exercise.8 Though these two agencies recommend a slightly different amount of exercise, the clear overall message, after consulting with one’s health care provider, is that all Americans are recommended to exercise in a consistent and frequent manner.

**Isometric Exercise**

In *isometric, or resistance, exercise*, sustained muscle contraction is generated against a stable load with no change in the length of the involved muscle group or joint movement. It involves activities, such as weight lifting and repeated movement against low to moderate resistance, that improve overall muscle strength and tone and build muscle mass. Although resistance training has long been accepted as a means of developing strength and muscle mass, more of its advantages have only recently been linked to beneficial health factors for people with chronic diseases.2

Despite the fact that the mechanisms may differ, both aerobic exercise and resistance training have similar effects on bone density, glucose tolerance, and insulin sensitivity. For weight control, aerobic exercise is considered a calorie burner. Resistance training assists the body in expending calories through an increase in lean body mass and basal metabolism. Many leisure and occupational tasks require isometric muscle efforts, often involving the arms rather than the legs. Because the blood pressure response to resistance exercise is proportionate to the maximal voluntary contraction as well as muscle mass involved, increased muscle strength results in an attenuated heart rate and blood pressure response to a given load.

**Flexibility Exercise**

In contrast to aerobic and resistance exercises, stretching as an isolated activity increases neither strength nor endurance but should be included in an overall fitness regimen. Considerable evidence suggests that stretching exercises increase tendon flexibility, improve joint range of motion, and enhance muscular performance.10 When properly performed, these exercises promote an overall improved general functioning. Thus, it is recommended that aerobic and resistance training be
accompanied by a stretching program that exercises the major muscle or tendon groups at least 2 to 3 days per week.¹⁰

**Physiologic and Psychological Responses of Exercise**

The physiologic and psychological benefits of exercise involve four major components:

1. Cardiopulmonary fitness
2. Increased muscle strength, flexibility, and endurance
3. Availability of energy substrates to meet the increased energy demands imposed by increased physical activity
4. Motivation and mental endurance

These benefits incorporate cardiopulmonary, neuromuscular, metabolic and thermal, and gastrointestinal responses; changes in hemostasis and immune function; and psychological behaviors that accompany physical activity and exercise.

**Remember** Ms. Iona Smith who was introduced to you in the unit opener case study? Iona was diagnosed with systemic lupus erythematosus after presenting with generalized joint discomfort, fatigue, and a malar rash on her face. She has experienced multiple losses and added stress this past year. Involvement in an exercise program developed specifically for her could help address many physical problems common to SLE sufferers, including cardiovascular disease, weakened bones and muscles, diminished aerobic exercise capacity, and overall fatigue. In fact, consistent exercise may significantly improve Iona’s mental health and her overall quality of life.

**Cardiopulmonary Responses**

The cardiopulmonary responses to exercise involve the circulatory functions of the heart and blood vessels and the gas exchange functions of the respiratory system. Collectively, they function to supply oxygen and energy substrates to the working muscles and exchange oxygen and carbon dioxide with the atmosphere. Cardiopulmonary or aerobic exercise involves repetitive and rhythmic movements and the use of large muscle groups and prepares the person to increase the duration of the more vigorous exercise.

The principal factor that determines how long and effectively a person will be able to exercise is the capacity of the heart, lungs, and circulation to deliver oxygen to the working muscles. The term *maximal oxygen consumption* (V˙O₂match others max) represents this principle. The VO₂max is determined by the rate at which oxygen is delivered to the working muscles, the oxygen-carrying capacity of blood, and the amount of oxygen extracted from the blood by the working muscles. It is measured as the volume of oxygen consumed, usually in liters or milliliters, per unit of time (i.e., liters/minute). The VO₂max is an important determinant of a person’s capacity to perform work and can increase up to 20-fold with strenuous exercise.¹¹ An exercise training program can accelerate the rate of increased VO₂max so that the trained athlete has a more rapid increase in cardiac output and skeletal muscle blood flow during the initial start of exercise.¹¹

The cardiovascular responses to exercise are regulated by output from centers in the central nervous system (CNS) and autonomic nervous system to the heart and blood vessels in tandem with local mechanisms that further regulate cardiac output and muscle blood flow.⁴ Recent research using brain mapping demonstrates specific areas of the brain, including the insular cortex and anterior cingulate cortex, that communicate with hypothalamic centers responsible for coordinating a pattern of increased sympathetic and decreased parasympathetic (vagal) outflow to the medullary cardiovascular centers¹² (Fig. 11.1). This leads to an increase in cardiac output and baroreceptor-mediated control of arterial blood pressure. Local control is derived from the release of metabolic end products (e.g., lactic acid) and local vasoactive factors that dilate blood vessels. Local factors in the coronary blood vessels mediate vasodilation, whereas increased sympathetic activity produces vasoconstriction of renal and gastrointestinal vessels, reducing blood flow to these organs.¹²

**Cardiac Output.** Exercise produces an increase in heart rate and stroke volume (amount of blood pumped with each heart beat), which in turn increases cardiac output. During exercise, the cardiac output may increase from a resting level of 4 to 8 L/minute to as high as 15 L/minute for women and 22 L/minute for men. The increase in heart rate is mediated through neural, hormonal, and intrinsic cardiovascular mechanisms. With anticipation of exercise, cardiovascular centers in the brain stem are stimulated to initiate an increase in sympathetic activity concomitant with an inhibition of parasympathetic mechanisms. Stimulation of the sympathetic nervous system produces an increase in heart rate and cardiac contractility. At the start of exercise, the heart rate increases immediately and continues to increase until a plateau is reached. This plateau, or steady-state heart rate, is maintained until exercise is terminated. Catecholamine release of epinephrine and norepinephrine assists in maintaining the heart rate.

Also contributing to the increased heart rate are mechanisms intrinsic to the heart. An increase in venous return stimulates right atrial stretch receptors that initiate an increase in heart rate, and an increase in ventricular filling stretches the myocardial fibers, resulting in a more forceful contraction and a more complete emptying of the ventricles with each beat through the Frank-Starling mechanism.⁴

**Blood Pressure and Blood Flow.** Blood pressure and blood flow also change with exercise. Increased sympathetic activity constricts the resistance vessels, leading to an increase in blood pressure, and it dilates the capacitance vessels in the visceral circulation, leading to an increase in venous return to the heart and maintenance of the cardiac output. It is important to note that the vasoconstriction produced by sympathetic innervation and circulating catecholamines (i.e., epinephrine)
Activity Tolerance and Fatigue

Respiratory Responses. The role of the respiratory system during exercise is to increase the rate of oxygen and carbon dioxide exchange. This takes place through a series of physiologic responses. With exercise, the respiratory rate increases four- to fivefold, tidal volume increases five- to sevenfold, and minute ventilation (respiratory rate × tidal volume) increases up to 20 to 30 times its resting value. With the increase in cardiac output, a greater volume of blood under slightly increased pressure is delivered to the pulmonary vessels in the lungs. This results in the opening of more pulmonary capillary beds, producing better alveolar perfusion and more efficient exchange of oxygen and carbon dioxide. In addition to pulmonary perfusion being enhanced during exercise, pulmonary ventilation is increased, resulting in a more optimal ventilation-perfusion ratio. This response is controlled by chemoreceptors—located in the brain stem, aorta, and carotid arteries—that monitor blood gases and pH. During exercise, decreases in blood oxygen and pH and increases in carbon dioxide stimulate these receptors, producing an increase in both the rate and depth of respiration.

Neuromuscular Responses

The integration of the neurologic and musculoskeletal systems is essential for body movement and participation in activity. To initiate and sustain increased activity, muscle strength, flexibility, and endurance are needed. Muscle strength is
defined as the ability of muscle groups to produce force against resistance. Flexibility involves the range of movement of joints, and muscle endurance refers to the ability of the body or muscle groups to perform increased activity for an extended time.

Types of Muscle. Skeletal muscle consists of two distinct types of muscle fibers based on differences in their size, speed, contractile properties, endurance, and metabolic characteristics: red (dark) slow-twitch (type I) and white (light) fast-twitch (type II) muscle fibers. Both heredity and activity influence the distribution of fast-twitch and slow-twitch fibers. Heredity appears to contribute to differences in muscle fiber composition, such that some people have considerably more fast-twitch than slow-twitch fibers, and others have more slow-twitch than fast-twitch fibers. This could determine, to some extent, the area of athletics for which a person is best suited.

The slow-twitch fibers, which are smaller than the fast-twitch fibers, tend to produce less overall force but are more energy efficient than fast-twitch fibers. They are better suited biochemically to perform lower-intensity work for prolonged periods. These fibers have a high oxidative capacity as a result of high concentrations of mitochondria and myoglobin. Slow-twitch fibers are highly fatigue resistant and ideally suited for prolonged aerobic exercise or activity. Examples of exercising that uses slow-twitch fibers are long distance running, swimming, and cycling where endurance is desired. Slow-twitch fibers predominate in the large muscle groups such as the leg muscles. Therefore, they play a major role in sustaining activity during prolonged exercise or endurance activities. Periods of sustained inactivity, such as prolonged immobility or bed rest, primarily affect slow-twitch fibers, which quickly decondition.

Iona would benefit greatly from a consistent aerobic exercise program, such as swimming or walking. She should also engage in some resistance training, such as lifting light weights, in order to build muscle strength. However, Iona’s exercise regimen should be closely supervised, because her disease affects her ability to perform both aerobic and resistance exercise. Close supervision, and perhaps working out in a group, would help her to adhere to an exercise program.

In contrast to slow-twitch fibers, fast-twitch fibers are larger and better suited for high-intensity work, but they fatigue more easily. These fibers have high myosin adenosine triphosphatase (ATPase) activity, few mitochondria, low myoglobin concentration, and high glycolytic capacity, resulting in dependence on anaerobic metabolism to supply adenosine triphosphate (ATP) for energy. Fast-twitch fibers predominate during activities in which short bursts of intense energy are required, such as sprinting or weight lifting. Anabolic steroids can enhance fast-twitch fiber activity.

People with heart failure (HF) typically experience symptoms of breathlessness, exertional fatigue, and exercise intolerance resulting in atrophy of skeletal muscles. When these people engage in exercise, there is a shift toward using fast-twitch muscle fibers. This causes an early dependence on anaerobic metabolism and excessive intramuscular acidification that leads to increased fatigability. The increased reliance on anaerobic metabolism and subsequent vasoconstrictor response can also lead to an increase in afterload work for an already compromised left ventricle. Thus, it is imperative that people with HF have their exercise regimens monitored closely.

Muscle Blood Flow. During aerobic activity, working muscles use 10 to 20 times more oxygen than nonworking muscles. This increased oxygen demand is met by an increase in cardiac output and muscle blood flow. Skeletal muscles receive 85% to 95% of the cardiac output during aerobic activities and only 15% to 20% of the cardiac output at rest. The increased blood flow is achieved through two mechanisms: dilation of blood vessels in the working muscles and constriction of those in organs of low priority. Increased blood flow to working muscles is achieved by relaxation of the arterioles and the precapillary sphincters. Chemical changes such as decreased oxygen and pH and increased levels of potassium, adenosine, carbon dioxide, and phosphate contribute to the vasodilation during prolonged exercise and recovery from exercise. Increased venous blood flow and central venous pressure are enhanced by the alternate contraction and relaxation of working muscles.

Another mechanism that increases blood flow to the working muscles is the diversion of blood from organs such as the kidneys and gastrointestinal structures that are less active than the working muscles. The amount of blood flow diverted from the visceral organs is proportional to the level of exercise, and as exercise is increased, more blood is diverted to working muscles.

Metabolic and Thermal Responses
Skeletal muscles hypertrophy and undergo other anatomic changes in response to exercise training. “Trained muscles” have an increased number of capillaries surrounding each muscle fiber that facilitates the delivery of oxygen to the working muscle cells during exercise. They are able to use oxygen more efficiently, probably because of enhanced enzymatic activity that increases oxidative capacity. The mitochondria appear to adapt by increasing the transport of oxygen and other substrates to the inner regions of the muscle fiber.

Unlike other tissues in the body, skeletal muscles switch between virtual inactivity when they are relaxed and using only minimal amounts of ATP, to extremes of physical activity during which they use ATP at a rapid rate. However, they have only enough ATP to power contraction for a few seconds. If strenuous exercise is to continue beyond this time, additional sources of ATP must be generated. The ATP that is used to power muscle contraction is obtained from three sources: creatine phosphate, glycogen, and fatty acids. Much like ATP, creatine phosphate (sometimes referred to as phosphocreatine) contains high-energy phosphate bonds. It is unique to muscle fibers and is 8 to 10 times as abundant as ATP. Creatine is a small, amino acid–like molecule that is both synthesized in the body and derived from foods (Fig. 11.2). The enzyme creatine
converted to heat. Under normal resting conditions, the body is able to maintain its temperature within a set range. It does this by two mechanisms. The first mechanism used by the body to regulate temperature is to change blood flow to the skin. When the blood vessels of the skin dilate, warm blood is shunted from the core tissues and organs to the skin surface, where heat is lost more easily to the surrounding environment. The second mechanism is through sweating, in which the evaporation of sweat from the skin surface contributes to the loss of body heat. Depending on training level and environmental conditions, the body may have difficulty regulating its temperature during vigorous exercise. With sufficient training, the body adapts by increasing the rate of sweat production. As temperature regulation improves with training, the trained person begins to sweat sooner, often within 1 to 2 minutes of the start of exercise. Sweat production begins even before the core temperature rises, and a cooling effect is initiated soon after the start of exercise; the sweat produced is more dilute than that produced by a nontrained person. Sweat normally contains large amounts of sodium chloride; production of a dilute sweat allows evaporative cooling to take place while sodium chloride is conserved.

**Gastrointestinal Responses.** The gastrointestinal system is affected by intense physical activity. During intense physical activity, blood flow is shifted to the working muscles, resulting in decreased blood flow to the gastrointestinal tract. This can lead to decreased stomach motility and impaired digestion and absorption of nutrients. The decrease in gastrointestinal blood flow can also result in decreased sensitivity to food, leading to decreased appetite and decreased calorie intake.

**Temperature Regulation.** Almost all the energy released from metabolic processes involved in muscle contraction is converted to heat. Under normal resting conditions, the body is able to maintain its temperature within a set range. It does this by two mechanisms. The first mechanism used by the body to regulate temperature is to change blood flow to the skin. When the blood vessels of the skin dilate, warm blood is shunted from the core tissues and organs to the skin surface, where heat is lost more easily to the surrounding environment. The second mechanism is through sweating, in which the evaporation of sweat from the skin surface contributes to the loss of body heat. Depending on training level and environmental conditions, the body may have difficulty regulating its temperature during vigorous exercise. With sufficient training, the body adapts by increasing the rate of sweat production. As temperature regulation improves with training, the trained person begins to sweat sooner, often within 1 to 2 minutes of the start of exercise. Sweat production begins even before the core temperature rises, and a cooling effect is initiated soon after the start of exercise; the sweat produced is more dilute than that produced by a nontrained person. Sweat normally contains large amounts of sodium chloride; production of a dilute sweat allows evaporative cooling to take place while sodium chloride is conserved.

**Nutritional and Hydration Status.** To supply the energy needed for increased activity, a person must consume a balanced diet and have adequate hydration. Although proteins are not used for energy sources during increased activity, they have an essential role in the building and rebuilding of tissues and organs. During increased activity and exercise, it is essential that a person maintain adequate hydration. Increased activity can result in loss of fluids from the vascular compartment. If this is allowed to progress, the person may experience severe dehydration that may lead to vascular collapse. Before and during vigorous activity, a person should replenish body fluids with water and electrolyte solutions.

**FIGURE 11.2 • The creatine phosphokinase (CK) reaction.** (A) Creatine phosphate transfers its phosphate group to ADP to generate ATP. When ATP is abundant, this reaction goes in reverse to regenerate creatine phosphate molecules at the expense of ATP. (B) Pyruvate is generated by the glucose produced by glycogen breakdown. Pyruvate can then be converted to lactic acid. (C) Mitochondria are also responsible for producing ATP from pyruvate, amino acids, or fatty acids. (From McConnell T. H., Hull K.L. (2011) Human form human function: Essentials of anatomy & physiology (p. 244). Philadelphia, PA: Lippincott Williams & Wilkins.)
is shunted away from the gastrointestinal tract toward the active skeletal muscles. As a result, gastrointestinal motility, secretory activity, and absorptive capacity are decreased. This can result in heartburn or reflux, vomiting, bloating, stomach pain, and gastrointestinal bleeding. It may also cause cramping, urge to defecate, and diarrhea. Although athletes may experience these symptoms, they are usually transient and do not have an effect on long-term health. Light and moderate exercise can benefit people with inflammatory bowel disease and liver disease. Evidence suggests that physical activity improves gastric emptying and lowers the risk of colon cancer and reduces the risks for diverticulosis, gastrointestinal hemorrhage, and inflammatory bowel disease.

Hemostasis and Immune Function
Increased physical activity affects both hemostasis and the immune system. Increased epinephrine levels stimulate increased fibrinolytic (i.e., breakdown of the fibrin strands in a blood clot) activity. Thus, regular strenuous exercise can result in increased fibrinolytic activity and a slowing of coagulation activity.

The response of the immune system to exercise is varied and depends on frequency, intensity, and duration of the exercise. The immune system is stimulated by regular, moderate exercise and impaired with regular, repetitive, intense exercise. A period of moderate-intensity exercise has been found to boost the immune system for several hours by producing an increase in circulating white blood cells, including neutrophils and lymphocytes. Of special note is the increased activity of natural killer cells. Chronic, intense, and exhausting exercise produces different effects on the immune system. Elevation in body temperature, cytokine release, and increased levels of various stress-related hormones (e.g., epinephrine, growth hormone, cortisol) may result in a temporary depression of the body’s innate immune defenses. Strenuous exercise alters mucosal immunity of the upper respiratory tract. This may explain why elite athletes are susceptible to illness, especially upper respiratory tract infections. Strenuous exercise also lowers the availability of the nonessential amino acid glutamine, which serves as an energy source for lymphocytes and macrophages and general immunocompetence.

**Psychological Responses**
There is a mental component to the performance of increased activity and exercise. The mental aspect entails the motivation to initiate an activity, or exercise program, and the dedication to incorporate the regimen into one’s lifestyle. Positive effects of regularly performed exercise include increased energy and motivation, positive self-image and self-esteem, decreased anxiety, and better management of stress.

**Assessment of Activity and Exercise Tolerance**
A person’s ability to tolerate exercise and perform work can be assessed in several ways. One way is by having the person report his or her perceived response to different types of physical activity or exercise. This method is particularly useful in assessing persons for activity intolerance and fatigue. Another method, exercise stress testing, is used to measure aerobic fitness.

**Activity Tolerance and Fatigue**
One method of assessing activity tolerance involves the administration of a screening tool in which participants describe their normal activities, their perceived level of activity tolerance, or their level of fatigue. An example of such a tool is the Human Activity Profile (HAP). The HAP originally was developed to assess the quality of life for persons participating in a rehabilitation program for chronic obstructive pulmonary disease. After investigating numerous physiologic and psychological measures, it was noted that the most important aspect of quality of life was the amount of daily activity the person was able to perform. The HAP consists of 94 items representing common activities that require known amounts of average energy expenditure. The person marks each item based on whether he or she is still able to perform the activity or has stopped performing the activity.

Another paper-and-pencil test is the Fatigue Severity Scale. This tool consists of nine statements that describe symptoms of fatigue (e.g., exercise brings on my fatigue; fatigue causes frequent problems for me; fatigue interferes with my work, family, social life). People are instructed to choose a number from 1 to 7 that best indicates their agreement with each statement. The tool is brief, easy to administer, and easily interpreted.

**Aerobic Fitness**
A number of tests are available to measure aerobic fitness, including the step test, and treadmill or bicycle ergometry. Often heart rate is used to estimate VO₂max without measuring oxygen consumption.

**Ergometry** is a procedure for determining physical performance capacity. The ergometer is a specific tool that imposes a constant level of work. A specified workload, expressed in terms of watts or joules per second, is imposed while the person performs the task. Two examples of ergometers include the bicycle ergometer and the treadmill ergometer. A bicycle ergometer is a stationary bicycle that has a friction belt attached. The front wheel of the bicycle is rotated, and the braking force of the belt can be adjusted to alter the workload. A treadmill ergometer is used more frequently to assess workload performance, especially cardiac function. During treadmill testing,
the person walks or runs on a moving belt. Changing the speed and incline of the treadmill alters the workload. This change usually is done in predetermined stages. During treadmill testing, the heart rate and electrocardiogram are monitored continuously, and the blood pressure is checked intermittently. Usually, the person being tested continues to exercise, completing successive stages of the test, until exhaustion intervenes or a predetermined or maximal heart rate is reached.

Maximal heart rate is estimated by age. Tables of maximal heart rate by age are available, but as a general rule, the predicted maximal heart rate can be estimated by subtracting age from 220 (e.g., the target heart rate for a 40-year-old person would be 180 beats/minute). The person may continue to exercise until the predicted maximum heart rate is achieved or until 85% to 90% of the predicted maximal rate is reached.

**Metabolic Equivalents.** Metabolic equivalents (METs), which are multiples of the basal metabolic rate, are commonly used to express workload at various stages of work. The energy expended in a resting position is equivalent to 1 MET, and it changes as the type of activity performed (e.g., walking, running) changes. For example, walking at 4 miles/hour (mph), cycling at 11 mph, playing tennis (singles), or doing carpentry requires 5 to 6 METs. Running at 6 mph requires 10 METs, and running at 10 mph requires 17 METs. Healthy sedentary people seldom are able to exercise beyond 10 or 11 METs, whereas highly trained people are able to achieve workloads of 16 METs or greater. In people with CHD, workloads of 8 METs often produce angina.

During exercise stress testing, people are asked to rate their subjective responses to the exercise experience. A commonly used tool to measure the person’s perception of the amount of work being performed is the Borg rating of perceived exertion (RPE) scale, which is based on research that correlates heart rate to feelings of perceived exertion. The scale values range from 6 through 20 (e.g., 7 represents very, very light; 9, very light; 13, somewhat hard; 15, hard; and 19 very, very hard). The numeric values on the RPE scale increase linearly with workload, and the total scale reflects a 10-fold increase in heart rate. As the person is performing the exercise stress test, he or she is asked to select a number that best corresponds to his or her feelings of exertion for the work being performed. The number chosen should be approximately 10 times the heart rate (e.g., if the person rates the exercise experience as a 7, the heart rate should be 70 beats/minute). A newer category of scale with ratio properties has been developed. The numbers used on this scale range from 0 to 10, with 0 representing nothing; 0.5, very, very weak; and 10, very, very strong. With this method, the expressions and the numbers they represent are placed in the correct position for a ratio scale. When using this scale in a phase II cardiac rehabilitation program, it is often recommended that people not exceed 30 beats/minute above their resting heart rate. Evidence shows that the RPE can positively predict both the physiological demands of an exercise and one’s performance in a specific exercise activity.

### Exercise and Activity Tolerance in Older Adults

As the population of older adults in Western societies increases, so does the concern over exercise and activity tolerance. It is anticipated that by 2020, people aged 60 and older will increase from 56,900,000 to 75,800,000. Regular exercise benefits older adults through a variety of physical and psychosocial components. These physical benefits include improved overall health and physical fitness, enhanced maximal aerobic capacity, prevention of a decline in the basal metabolic rate, gains in cerebral function, and improved balance and coordination. Psychologically, the older adult may experience a greater sense of well-being, increased opportunities for social interactions, lower rates of mortality, and fewer years of disability.

The capacity of older adults to undertake aerobic activities such as walking and running is adversely affected by advancing age. Current evidence supports a 5% to 15% decline per decade in VO\(_{\text{max}}\) in men and women beginning at 25 years of age. The decline in VO\(_{\text{max}}\) seems to be due to both central and peripheral adaptations. Reductions in maximal heart rate, stroke volume, and lean body mass all contribute to a reduced VO\(_{\text{max}}\).

In terms of skeletal muscle function, there is a decrease in muscle mass and strength, flexibility and range of joint movement, and muscle endurance. There is a decrease in size of the individual muscles that occurs with aging, particularly beyond 60 years of age. Muscle strength and mass reportedly decline 30% to 50% between 30 and 80 years of age.

The most important factor in muscle atrophy in older adults is the reduction in type II fibers and the size of the muscle fiber areas. Muscle mass loss is subordinate to an age-related denervation of type II fibers, which removes the trophic effect on the fibers, leading to atrophy. Type I fiber collaterals expand to some of the denervated type II fiber areas in an attempt to lessen muscle fiber loss. This leads to an increase in type I motor neuron units at the expense of type II fibers, resulting in a reduction in muscle mass and muscle strength. There is also a slowing of muscle contraction and rate of force development, and reduced ability to accelerate limb movement. Changes in the elastic and collagen fibers of tendons and ligaments lead to decreased flexibility and loss of mobility and stability of the joints.

As with exercise programs for younger adults, exercise programs for older adults should include an emphasis on aerobic activities, resistance training, flexibility or stretching exercises, and lifestyle changes. Resistance exercise, which improves muscle strength, is particularly important for older adults. Most of the variance of walking speed in older adults is related to leg strength, and increased strength has been shown to increase walking endurance and stair climbing. Flexibility training is also important because limited range of motion in the hip, knee, and ankle joints increases the risk of falls and contributes to age-related changes in gait. Lifestyle modification involves finding opportunities within a person’s existing
routines to increase physical activity (e.g., taking stairs rather than an elevator, parking farther from entrances).

IN SUMMARY

Physical activity and exercise denote the process of skeletal muscle movement and energy expenditure. There are two main types of exercise: aerobic and isometric. **Aerobic, or endurance, exercise** involves rhythmic changes in muscle length and increases the ability of muscles to use oxygen more efficiently so that the body can do more work with less cardiac and respiratory effort. **Isometric, or resistance, exercise** involves the generation of force against low to moderate resistance, improves overall muscle strength and tone, and builds muscle mass. Flexibility, or stretching, exercise promotes flexibility and improves range of motion of the joints.

The body reacts to exercise by a series of physiologic responses that increase its level of performance. Heart rate, cardiac output, and stroke volume increase to deliver more blood to working muscles; minute ventilation and diffusion of oxygen and carbon dioxide increase to provide oxygen more efficiently to meet the rising metabolic demands; and local changes in the arterioles and capillaries contribute to enhanced perfusion of the working muscles. The **maximal oxygen consumption** (VO$_{2}$max), which is the volume of oxygen consumed (i.e., liters/minute), is an important determinant of the person’s capacity to perform work. Activity and exercise tolerance can be assessed in several ways, including through the use of paper-and-pencil tests that measure subjective responses or through tests such as bicycle or treadmill ergometry that measure heart rate, VO$_{2}$max, and other responses during exercise.

The capacity of older adults to undertake aerobic activities such as walking and running is adversely affected by reductions in maximal heart rate, stroke volume, and VO$_{2}$max, along with a decrease in muscle mass and strength, flexibility and range of joint movement, and muscle endurance. Exercise programs for older adults should include an emphasis on aerobic activities, resistance training, flexibility or stretching exercises, and lifestyle changes.

**Activity intolerance** can be viewed as not having sufficient physical or psychological energy reserve to endure or complete required or desired daily activities. Fatigue is the sensation that comes with having exhausted those energy reserves. It is a state that is experienced by everyone at some time in his or her life. Fatigue can be a normal physical response, such as that following extreme exercise in healthy people, or it can be a symptom that is experienced by people with limited exercise reserve, such as people with cardiac or respiratory disease, anemia, or malnutrition, or those on certain types of drug therapy. Fatigue also may be related to lack of sleep or mental stress.

Like dyspnea and pain, fatigue is a subjective symptom. It often is described as a feeling of just not feeling right and having a lack of energy and motivation to do anything. Fatigue is different from the normal tiredness that people experience at the end of the day. Tiredness is relieved by a good night’s sleep, whereas fatigue persists despite sufficient or adequate sleep. Although fatigue is one of the most common symptoms reported to health care professionals, it is one of the least understood of all health problems. Fatigue cannot be explained using a measurement such as amount of activity or exercise.\(^\text{29}\)

The physiologic basis of fatigue includes factors such as diaphragmatic, motor, and neurologic mechanisms. Diaphragmatic fatigue occurs in both acute and chronic respiratory conditions where the force and duration of muscle work exceeds muscle energy stores. Neuromuscular fatigue involves the loss of maximal capacity to generate force during exercise.

**ACTIVITY INTOLERANCE AND FATIGUE**

- **Acute fatigue** is muscle fatigue with a rapid onset and duration limited to the duration of the exercise. The time it takes to develop acute fatigue at any level of exercise depends on conditioning.
- **Chronic fatigue syndrome (CFS)** is characterized by disabling fatigue and many nonspecific symptoms, including cognitive impairments, sleep disturbances, and musculoskeletal pain. The etiology of CFS is unknown, but it is associated with several chronic diseases such as fibromyalgia, depression, and irritable bowel syndrome.

**Mechanisms of Fatigue**

The origin or cause of fatigue can be physiologic, psychological, pathologic, or unknown (e.g., CFS or myalgic encephalomyelitis). It can be caused by environmental factors (e.g., excessive noise, temperature extremes, changes in weather); drug-related incidents (e.g., use of tranquilizers, alcohol, toxic chemical exposure); treatment-related causes (e.g., chemotherapy, radiation therapy, surgery, anesthesia,
diagnostic testing); physical exertion (e.g., exercise); and psychological factors (e.g., stress, monotony).

Clinically, fatigue can be described as to how it began, what seems to trigger it, and how it is managed. This information can sometimes assist in determining the etiology of the pain. It is thought that both acute and chronic fatigue can exist in the same person, similar to acute and chronic pain.

**Acute Physical Fatigue**

Acute fatigue has a rapid onset and is often defined as muscle fatigue associated with increased activity, or exercise, that is carried out to the point of exhaustion. It also is frequently associated with a viral or bacterial infection and may present with other systemic symptoms such as fever or malaise. If it is associated with muscle fatigue, is relieved shortly after the activity ceases and serves as a protective mechanism. Physical conditioning can influence the onset of acute fatigue. People who engage in regular exercise compared with sedentary people are able to perform an activity for longer periods before acute fatigue develops. They probably are able to do so because their muscles use oxygen and nutrients more efficiently and their circulatory and respiratory systems are better able to deliver oxygen and nutrients to the exercising muscles.

Acute physical fatigue occurs more rapidly in deconditioned muscle. For example, acute fatigue often is seen in people who have been on bed rest because of a surgical procedure or in people who have had their activity curtailed because of chronic illness, such as heart or respiratory disease. In such cases, the acute fatigue often is out of proportion to the activity that is being performed (e.g., dangling at the bedside, sitting in a chair for the first time). When resuming activity for the first time after a prolonged period of bed rest or inactivity, the person may experience tachycardia and hypotension. Unless these parameters are changed by medications such as β-adrenergic blocking drugs, heart rate and blood pressure become particularly sensitive indicators of activity tolerance or intolerance.

Another example of acute fatigue is that which occurs in people who require the use of assistive devices such as wheelchairs, walkers, or crutches. The upper arm muscles are less well adapted to prolonged exercise than the leg muscles. This is because arm muscles are primarily composed of type II muscle fibers. Type II muscle fibers, which are used when the body requires short bursts of energy, fatigue quickly. As a result, people who use wheelchairs or a pair of crutches may quickly experience fatigue until their arms become conditioned to the increased activity.

**Chronic Fatigue**

Chronic fatigue differs from acute fatigue in terms of onset, intensity, perception, duration, and relief. Chronic fatigue is much more complex and difficult to diagnose. There are several possible causes such as hypothyroidism, anemia, heart disease, Lyme disease, fibromyalgia, lung disease, electrolyte dysfunction, tuberculosis, hepatitis, and cancer. It is one of the more common problems experienced by people with chronic health problems (Table 11.1). In the primary care

</tbody>
</table>
setting, many people complain of chronic fatigue. Chronic fatigue with HF or emphysema is accepted given the pathophysiology of these conditions. Others may have a transient fatigue that can be managed with vitamin or other medication supplementation. The remainder will either meet the criteria for diagnosis of CFS or will remain undiagnosed.

Although acute fatigue often serves a protective function, chronic fatigue does not. It limits the amount of activity that a person can perform and may interfere with employment, the performance of activities of daily living, and the quality of life in general. Although fatigue often is viewed as a symptom of anxiety and depression, it is important to recognize that these psychological manifestations may be symptoms of the fatigue. For example, people with persistent fatigue due to a chronic illness may have to curtail their work schedules, decrease social activities, and limit their usual family responsibilities. These lifestyle changes may be the reasons for the depression rather than the depression being a cause of the fatigue.

Chronic fatigue occurs across a broad spectrum of disease states. It is a common complaint of persons with cancer, cardiac disease, end-stage renal disease, chronic lung disease, hepatitis C, arthritis, human immunodeficiency virus (HIV) infection and acquired immunodeficiency syndrome (AIDS), and neurologic disorders such as multiple sclerosis, postpolio syndrome, and Parkinson disease.

Chronic fatigue is almost a universal phenomenon in people with cancer. Nineteen to ninety-six percent of people undergoing treatment for cancer experience fatigue. Additionally, posttreatment, 19% to 86% of people experience fatigue. Cancer-related fatigue may be caused by the disease itself, or it may be caused by treatment. Cancer-related fatigue involves a number of physiologic, sensory, affective, and cognitive dimensions. There is often a sensation of feeling unusually tired with generalized weakness and a greater need for rest. There may also be a disturbing lack of motivation, anxiety, and sadness as well as an inability to concentrate or difficulty in thinking.

There are several types of cancer-related factors that may cause fatigue, the most prominent of which are factors related to energy imbalance such as the following disorders: anemia, cachexia, stress, pain, infection, medications, and metabolic disorders. The cytokine theory of cancer-related fatigue is based, at least in part, on the observation that people receiving agents such as interferon-α as part of their treatment plan experienced devastating fatigue that appears dose limited. Interferon-α and other agents used to treat cancer also influence the release of other cytokines that are related to fatigue. Cancer cells and the immune system appear to produce or express a number of cytokines with the potential for manufacturing many of the factors that contribute to fatigue particularly interleukin-1 beta and tumor necrosis factor alpha (TNF-α). One of these cytokines, TNF-α, is thought to be associated with morning fatigue and sleep disturbances. Another study demonstrates that by having people with cancer perform specific skeletal exercise causes the release of interleukin-6, which can decrease the levels of TNF-α and interleukin–1 beta.

Management of Chronic Fatigue

Many of the pathologic factors associated with fatigue, including insomnia, anemia, psychological stress, and weakness, respond to appropriate treatment measures. Anemia, which is common among people with HIV/AIDS, people with end-stage renal disease, and people with cancer receiving chemotherapy, causes fatigue by interfering with the oxygen-carrying capacity of the blood. It is sometimes treated with recombinant forms of erythropoietin (epoetin alfa), an endogenous hormone normally produced by the kidney. Insomnia, which occurs for a number of reasons, including anxiety and depression, hot flashes, nocturia, and pain, is often amenable to nonpharmacologic and pharmacologic methods of treatment. Psychological disturbances, such as anxiety and depression, which are frequently associated with fatigue, can be treated with selected pharmacologic agents. Another cause of fatigue is loss of muscle mass, muscle strength, and endurance. It may be that the person needs to have a thorough physical examination with laboratory studies to determine if there are any musculoskeletal or neurologic findings that may be impacting the person’s stamina such as myositis, Guillain-Barre, or polymyalgia. Or perhaps the person needs to exercise daily and in a consistent manner.

Chronic Fatigue Syndrome

CFS is a condition of disabling fatigue of at least 6 months’ duration that is typically accompanied by an array of self-reported, nonspecific symptoms such as cognitive impairments, sleep disturbances, and musculoskeletal pain. In the late 20th century and now into the 21st century, the disorder continues to be a relatively common problem.

Definition. Because the etiology of CFS is unknown, there are no biologic markers for the diagnosis of CFS, and there are no definitive treatments. Furthermore, the overlap of symptoms of CFS with other functional disorders such as fibromyalgia, multiple chemical sensitivities, depression, and irritable bowel syndrome, which also are characterized by fatigue, complicates the ability to define the syndrome with any degree of certainty. In fact, CFS may describe a group of similar symptoms that develop with different pathophysiologic disturbances.

Because of the need for diagnostic criteria, the case definition for CFS was established in 1988 by the CDC and revised through its International Chronic Fatigue Syndrome Study Group in 1994. To be classified as CFS, the fatigue must be clinically evaluated, cause severe mental and physical exhaustion, and result in a significant reduction in the individual’s proromobid activity level. In addition, there must be evidence of the concurrent occurrence of four of the following eight symptoms: sore throat, tender cervical or axillary lymph nodes, muscle pain, multijoint pain without swelling or redness, headaches, unrefreshing sleep, and postexertional malaise lasting more than 24 hours. The fatigue and concurrent symptoms must be of 6 months’ duration or longer. Table 11.2 illustrates examples of conditions that may mimic CFS. Charts 11.1 and 11.2 outline the CDC’s symptoms of CFS and the criteria for diagnosis of CFS.

**CHART 11.1 CDC SYMPTOMS OF CHRONIC FATIGUE SYNDROME**

The fatigue of CFS is accompanied by characteristic symptoms lasting at least 6 months. These symptoms include:
- Difficulties with memory and concentration
- Problems with sleep
- Persistent muscle pain
- Joint pain (without redness or swelling)
- Headaches
- Tender lymph nodes
- Increased malaise (fatigue and sickness) following exertion
- Sore throat

**Other Symptoms**
The symptoms listed above are the symptoms used to diagnose this illness. However, many people with CFS may experience other symptoms, including:
- Irritable bowel
- Depression or psychological problems (irritability, mood swings, anxiety, panic attacks)
- Chills and night sweats
- Visual disturbances (blurring, sensitivity to light, eye pain)
- Allergies or sensitivities to foods, odors, chemicals, medications, or noise
- Brain fog (feeling like you’re in a mental fog)
- Difficulty maintaining upright position, dizziness, balance problems, or fainting

It’s important to tell your health care professional if you’re experiencing any of these symptoms. They may co-occur in CFS, or they may indicate that you have another treatable disorder.

Pathophysiology. Theories of the pathogenesis of CFS include genetic expression, infections, stress and prior psychological disorders, a dysfunction in the hypothalamic–pituitary–adrenal axis, nutritional deficiencies, or increased oxidative and nitrosative stress.34 Despite much research and the development of several theories, the underlying pathophysiology of CFS remains elusive. Many people with CFS attribute the onset of their disease to an influenza-like infection. Thus, the link between infectious agents such as Epstein-Barr virus, human herpesvirus 6, Candida yeast, Borrelia bacteria, and others has been extensively studied. To date, however, none of these agents has been conclusively linked in a cause-and-effect relationship with the development of CFS.34 It is hypothesized that the immune system may overreact to an environmental agent (most likely an infectious agent) or internal stimuli and be unable to self-regulate after the infectious insult is over.

Psychological disorders often are associated with CFS, especially anxiety and depression, but this is difficult to evaluate. People with CFS are more likely than the general population to have experienced a psychological disorder such as major depression or panic disorder before the development of CFS. However, it also is true that a significant proportion of those people with CFS have not had such episodes, either before or after the development of CFS.34

Abnormalities of the hypothalamic–pituitary–adrenal axis, such as attenuated activity of corticotropin-releasing hormone and changes in the circadian rhythm of cortisol secretion, have been documented. Although low thyroid hormones, dehydroepiandrosterone (DHEA), and cortisol levels have been found in people with CFS, these parameters are not decreased in all people with CFS.34

Genetic links with CFS include a gene associated with Huntington disease neurodegenerative protein, abnormalities in the way genes affect mitochondrial-cell energy production, and connections to depression and anxiety.34 Additionally, connections with CFS individuals and a persistent inflammatory state have been determined.35

Clinical Manifestations. One of the most important findings in people with CFS is the complaint of fatigue. Often, the symptom of fatigue is preceded by a cold or flu-like illness. Frequently, the person describes the illness as recurring, with periods of exacerbations and remissions. With each subsequent episode of the illness, the fatigue increases.

Physical findings include low-grade fever. The fever is intermittent and occurs only when the illness recurs. Other findings include nonexudative pharyngitis, palpable and tender cervical lymph nodes, a mildly enlarged thyroid gland, wheezing, splenomegaly, myalgia, arthralgia, and heme-positive stool with subsequent negative sigmoidoscopy.

Psychological problems include impaired cognition, which the person describes as an inability to concentrate and perform previously mundane tasks. There are reports of mood and sleep disturbances, balance problems, visual disturbances, and various degrees of anxiety and depression.

Diagnosis and Treatment. The diagnosis of CFS is based on integration of the entire clinical picture of the person’s symptoms, physical assessment findings, and the results of diagnostic tests. Laboratory investigations are used to detect other disorders. Usually the final diagnosis is based on the definition of CFS provided by the CDC35 (see Chart 11.1). There is some discussion that people with less associated symptoms of CFS may be able to be accurately diagnosed with CFS at an earlier state.36

Because there is no known cause of CFS, current treatment tends to remain symptomatic, with a focus on management rather than cure. It centers on education, emotional support, treatment of symptoms, and overall management of general health. Symptom management includes development of an exercise program that helps the person regain strength. Along with a structured activity program, people should be encouraged to be as active as possible as they resume their activities of daily living.

A holistic approach to the treatment of CFS is essential. With proper treatment and support, most people with CFS demonstrate improvement. However, relapses can occur. People diagnosed with CFS must continue to receive follow-up care and treatment on a regular basis. Local and national support groups are available for people who experience CFS.

---

**Chart 11.2 CRITERIA FOR DIAGNOSING CHRONIC FATIGUE SYNDROME**

Your clinician should consider a diagnosis of CFS if these two criteria are met:

- Unexplained, persistent fatigue that’s not due to ongoing exertion, isn’t substantially relieved by rest, is of new onset (not lifelong), and results in a significant reduction in previous levels of activity
- Four or more of the following symptoms are present for 6 months or more:
  - Impaired memory or concentration
  - Postexertional malaise (extreme, prolonged exhaustion and sickness following physical or mental activity)
  - Unrefreshing sleep
  - Muscle pain
  - Multijoint pain without swelling or redness
  - Headaches of a new type or severity
  - Sore throat that’s frequent or recurring
  - Tender cervical or axillary lymph nodes

Bed rest and immobility are associated with multiple adverse outcomes, such as generalized weakness, orthostatic intolerance, atelectasis, pneumonia, thromboemboli, urinary retention, constipation, muscle atrophy, osteoporosis, and impaired sensory perception. This section of the chapter focuses on the physiologic changes that occur with bed rest and immobility and the interventions to counteract their effects.

**Physiologic Effects of Bed Rest**

The supine position that often accompanies immobility and bed rest interferes with the effects of gravity and exercise stimuli (Fig. 11.3). While in the upright position, the body compensates for the effects of gravity in a variety of ways. The skeletal muscles contract and exert pressure against veins and lymph vessels, counteracting the hydrostatic effects of gravity that cause blood and fluid to pool in the lower extremities. Movement against the forces of gravity maintains muscle tone, and bones remain stronger because longitudinal weight bearing keeps essential minerals, such as calcium, inside the structure of the bone.

**Cardiovascular Responses**

After a period of bed rest and assumption of the supine position, the cardiovascular system exhibits changes that reflect the loss of gravitational and exercise stimuli. These changes include

1. A redistribution and change in blood volume
2. Increased cardiac workload
3. Orthostatic hypotension
4. Venous stasis with the potential for development of deep vein thrombosis (DVT)

**Redistribution and Change in Blood Volume.** One of the most striking responses to assumption of the supine position during bed rest is the redistribution and change in blood volume. In the supine position, approximately 500 mL of blood is redistributed from the lower extremities to the central circulation. Most of this blood is diverted to the thoracic cavity; a smaller portion is diverted to the arms and head.

**IN SUMMARY**

Fatigue is a nonspecific, self-recognized state of physical and psychological exhaustion. It results in the person’s not being able to perform routine activities and is not relieved with sleep or rest. Acute fatigue results from excessive use of the body or specific muscle groups and often is related to depletion of energy sources. Chronic fatigue often is associated with a specific disease or chronic illness and may be relieved when the effects of the disease are corrected. CFS is a complex illness that has physiologic and psychological manifestations. It is characterized by debilitating fatigue. Diagnosis often is made by a process of elimination, and treatment requires a holistic approach.

**KEY POINTS**

**BED REST AND IMMOBILITY**

After completing this section of the chapter, you should be able to meet the following objectives:

- Describe the effects of immobility and prolonged bed rest on cardiovascular, pulmonary, renal, metabolic, musculoskeletal, gastrointestinal, and sensory function.
- Describe the time course of the physiologic changes associated with immobility and prolonged bed rest.

Bed rest is one of the oldest and most commonly used methods of treatment for various medical conditions. Historically, it was felt that bed rest was imperative for people convalescing from just about any illness. For example, before the 1940s, bed rest was prescribed for 2 weeks after childbirth, 3 weeks after herniorrhaphy, and 4 to 6 weeks after myocardial infarction. It was believed that the complex biochemical and physical demands of physical activity diverted energy from the restorative and reparative processes of healing. However, the cardiovascular, musculoskeletal, integumentary, and pulmonary manifestations of bed rest were identified, and bed rest quickly was deleted from standard care procedures. Today, it is known that bed rest is the antithesis of exercise and mobility and the immobilizing effects of bed rest cause serious systemic problems. Being immobile or on prolonged bed rest defies the active use of skeletal muscles, movement against gravity, conservation of body fluids, normal distribution of blood flow, and maintenance of cardiopulmonary reserves. Immobility may be dictated by an injury that requires stabilization to facilitate the healing process, or it may result from conditions that limit physical reserve. The effects of immobilization can be restricted to a single extremity that is encased in a plaster cast; involve both legs, as in a person confined to a wheelchair; or involve the entire body, as in a person confined to bed rest.
Increased Cardiac Workload. A major cardiovascular manifestation of bed rest is an increased workload on the heart. The increase in thoracic blood volume that occurs on assumption of the supine position results in an increase in central venous pressure and left ventricular end-diastolic volume and an increase in stroke volume and cardiac output through the Frank-Starling mechanism. In the supine position, the normal cardiac output is 7 to 8 L/minute, compared with a cardiac output of 5 to 6 L/minute for a person in the standing position. Initially, the increase in cardiac output is accompanied by a slight decrease in heart rate and systemic vascular resistance and maintenance of arterial blood pressure.

With extended periods of bed rest, there is an increase in venous distention. Venous distension leads to a decrease in venous return to the heart, along with a stabilization of the stroke volume and cardiac output. The heart rate, however, continues to increase. During periods of tachycardia, the diastolic filling time is decreased; as a result, the heart has to expend more energy and use more oxygen to perfuse vital organs and meet the metabolic demands of the body. This response is exaggerated when a person has to assume the upright position and begin activity after a prolonged period of bed rest. When a person begins submaximal exercise after prolonged bed rest, heart rate increases while stroke volume and cardiac output decrease. Between 5 and 10 weeks of reconditioning, exercise is required for return of heart rate, stroke volume, and cardiac output parameters to their levels before bed rest.38

Bed rest also affects fluid balance. The increase in central blood volume results in an inhibition of antidiuretic hormone and aldosterone, with a resultant water and sodium diuresis. In the supine position, diuresis begins on the first day with the shift of blood from the lower extremities to the thoracic cavity. The loss of water and sodium results in a loss of plasma volume. After approximately 4 days of bed rest, fluid losses reach an equilibrium. A possible explanation for this is that fluid is lost from the vascular compartment with a subsequent shift of fluid from the interstitial to the vascular fluid compartment.

Orthostatic Hypotension. During bed rest, the forces of gravity and hydrostatic pressure are removed from the cardiovascular system. After 3 to 4 days of bed rest, resumption of the upright position results in orthostatic or postural intolerance. Standing after prolonged bed rest results in a decrease in central blood volume. Decreases in stroke volume and cardiac output occur along with increases in heart rate and systemic vascular resistance. The signs and symptoms of postural intolerance include tachycardia, nausea, diaphoresis, and sometimes syncope or fainting.
The mechanism of orthostatic intolerance after bed rest involves multiple factors, including a decrease in vascular volume, a decline in skeletal muscle pump function, reduced sympathetic innervation of the resistance vessels, and resetting of the baroreceptors that control blood pressure. Because changes in plasma volume do not fully explain the orthostatic intolerance that occurs with bed rest, it is thought that the sympathetic nervous system may influence this response. It has also been suggested that the decrease in stroke volume that occurs with assumption of the upright position after bed rest may be due to a reduction in left ventricular size and distensibility that occurs in response to a decrease in loading conditions of the heart.

**Venous Stasis.** Venous stasis in the legs results from a lack of the skeletal muscle pump function that promotes venous return to the heart. The skeletal muscle pump function decreases after assumption of the supine position, and there is mechanical compression of veins from the position of the lower extremities against the bed. This increased pressure can cause damage to the vessel intima, predisposing to platelet adherence and clot formation.

The development of DVT is a major complication of bed rest. It is believed that three factors (often referred to as the *Virchow triad*) combine to predispose a person to DVT. These factors are:

1. Stasis of venous flow due to inactivity of the skeletal muscle pumps
2. A hypercoagulability state resulting from a decrease in vascular volume and an increase in blood viscosity and concentration of blood coagulation factors
3. Vessel injury to the endothelium resulting from external pressure against the veins

The development of DVT also predisposes to the development of pulmonary emboli. With resumption of activity, there is risk that large thrombi may dislodge, work their way through the circulatory system, and lodge in the pulmonary vessel.

**Pulmonary Responses**

Assumption of the supine position produces changes in lung volumes and the mechanics of breathing. Respiratory complications such as atelectasis, accumulation of secretions, hypoxemia, and pneumonia are all possible outcomes if a person is lying supine and on bed rest for more than 24 hours. In the supine position, breathing largely depends on the abdominal muscles rather than on movement of the chest cage. The diaphragm moves upward rather than downward, decreasing the size of the thoracic compartment, and chest and lung expansion are limited because of the resistance of the bed. As a result, the tidal volume and functional residual capacity are decreased, and the efficiency and effectiveness of ventilation are hindered. Thus, people on bed rest need to work harder to breathe, and consequently they take fewer deep breaths. If the person must be on bed rest, it would be better to put the person in a prone position if he or she could tolerate it.

A reduction in functional residual capacity predisposes to airway collapse, ventilation–perfusion inequalities, and impaired oxygen transport. Alveoli tend to collapse, resulting in areas of atelectasis and a decrease in the surface area for gas exchange. This may result in arteriovenous shunting with a concomitant decrease in arterial oxygenation. Also, poor fluid intake and dehydration may cause secretions to become thick and tenacious. Stasis of secretions provides an ideal medium for bacterial growth and increases the risk for development of pneumonia. Reduced activity and the recumbent position inhibit coughing, foster the retention of secretions, and adversely affect secretion distribution in the airways. Coughing and deep breathing are necessary to prevent accumulation of secretions and airway collapse.

**Urinary Tract Responses**

The kidneys are designed to function optimally with the body in the erect position (Fig. 11.4). The anatomy of the kidney is such that urine flows from the kidney pelvis by gravity, whereas the action of peristalsis moves urine through the ureters to the bladder. Prolonged bed rest affects the renal system by altering the composition of body fluids and predisposing to the development of kidney stones. In the supine position, urine is not readily drained from the renal pelvis. Bed rest also may predispose to urinary tract infections, urinary incontinence, and renal stones due to the prolonged lack of mobility.

A major complication of prolonged bed rest is the increased risk for development of kidney stones. Prolonged bed rest causes muscle atrophy, protein breakdown, and decalcification of bone with the development of hypercalcemia and hyperphosphatemia. Saturation of the urine with calcium salts (*i.e.*, calcium oxalate and calcium phosphate) coupled with urinary stasis increases the risk for the development of calcium-containing kidney stones. Dehydration further increases urine concentration of stone-forming elements and risk of kidney stone formation.

Urinary tract infections and incontinence also may occur. The cause of incontinence is inadequate emptying of the bladder while the person is in the supine position. This position
contributes to stagnation of urine in the bladder and may predispose the person to bladder and urinary tract infections.

**Musculoskeletal Responses**

Musculoskeletal responses to bed rest and immobility reflect changes associated with the loss of both gravitational and exercise stress. In addition to a loss of strength, muscles atrophy, change shape and appearance, and shorten when immobilized. Disuse atrophy can lead to loss of approximately one eighth of the muscle’s strength with each week of disuse.40 These changes affect individual muscle fibers and total muscle mass.

Immobilization also causes a reduction in force-generating capacity along with increased fatigability, primarily owing to a decrease in muscle mass and the cross-sectional area of muscle fiber.40 There also is a decrease in the oxidative capacity of the mitochondria. Because of the decreased oxidative capacity of the mitochondria, muscles fatigue more easily.40 The larger and the better trained the muscle, the faster the loss of muscle strength and the quicker the deconditioning occurs. Leg muscles tend to lose strength more rapidly than arm muscles, but it is not clear whether it is because legs are relatively better trained than arms, the legs have a larger muscle mass, or bed rest results in a greater decrease in activity for legs than arms.

Along with the muscle, the supporting connective tissues undergo changes when subjected to immobility or bed rest. Periarticular connective tissue, ligaments, tendons, and articular cartilage require motion to maintain health. Changes in structure and function of connective tissue become apparent 4 to 6 days after immobilization and remain even after normal activity has been resumed.

Muscle atrophy and disuse not only contribute to wasting and weakening of muscle tissue, they play a role in the development of joint contractures. A contracture is the abnormal shortening of muscle tissue and connective tissue, rendering the muscle highly resistant to stretch. Contractures occur when muscles do not have the necessary strength to maintain their integrity (i.e., their proper function and full range of motion). Contractures mainly develop over joints when there is an imbalance in the muscle strength of the antagonistic muscle groups. If allowed to progress, the contracture eventually involves the muscle groups, tendons, ligaments, and joint capsule. The joint becomes limited in its full use and range of motion and is more prone to develop a contracture.

Another consequence of prolonged immobility and bed rest for the musculoskeletal system is the loss of bone mineralization. Bone is a dynamic tissue that undergoes continual deposition and replacement of minerals in response to the dual stimuli of weight bearing and muscle pull. According to the Wolff law, the density of bone is directly proportional to the stress placed on it.

The maintenance of normal bone function depends on two types of cells: osteoblasts and osteoclasts. Osteoblasts function in building the osseous matrix of the bone, and osteoclasts function in the breakdown of the bone matrix. Osteoblasts depend on the stress of mobility and weight bearing to perform their function. During immobility and bed rest, the building of new bone stops, but the osteoclasts continue to perform their function. When bone experiences a lack of stress, as occurs with bed rest or immobility, there is a greater amount of bone resorption than bone formation, resulting in loss of bone mineralization or disuse osteoporosis.40 The degree to which bone demineralization can be reversed is not known; however, permanent loss of bone mass and osteoporosis can result from long-term immobilization.

Osteoporosis represents an increase in skeletal porosity resulting from reduced bone mass. The bones may easily compress and become deformed. Because of the lack of structural firmness, the bones may easily fracture. The best measure to prevent the occurrence of osteoporosis is to begin weight-bearing exercises as soon as possible. The type of exercise that is performed is particularly important because load magnitude influences bone density more than the number of load cycles.

**Metabolic, Endocrine, and Immune Responses**

**Metabolic Responses.** Metabolic and endocrine changes reflect the absence of both gravitational and exercise stimulation during bed rest and immobility. The basal metabolic rate drops in response to decreased energy requirements of the body. Anabolic processes are slowed, and catabolic processes become accelerated, which leads to nutritional imbalance with a negative nitrogen balance. People in a negative nitrogen balance experience nausea and anorexia, which contribute to the catabolic state.

**Endocrine Responses.** In general, bed rest results in an uncoupling of hormonal stimulation and target organ unresponsiveness. Thyroid hormone concentrations tend to fluctuate, and levels of other hormones such as insulin and cortisol tend to be reduced. A major hormonal change that occurs with prolonged periods of immobility is an increase in the serum parathyroid hormone (PTH) due to the hypercalcemia that occurs secondary to bed rest.

People who experience prolonged periods of bed rest often have changes in the circadian release of various hormones. Normally, insulin and growth hormone peak twice a day. In people who experienced 30 days of bed rest, a single daily peak of these hormones occurred. Other hormonal changes include an afternoon peak of epinephrine rather than the normal early morning peak, and an early morning peak of aldosterone rather than the usual noonday peak that is seen in normally active people.

The person on bed rest also experiences an impaired responsiveness to the actions of insulin. The reason for this intolerance is not due to lack of insulin, but rather to an increased resistance to the action of insulin that then results in a hyperglycemic and hyperinsulinemic state. Possible reasons for the unresponsiveness of glucose to hyperinsulinemia include defects in suppression of hepatic glucose production, defects in insulin stimulation of glucose uptake by peripheral tissues, or both. This induced insulin resistance may explain
the negative nitrogen balance seen in patients who experience prolonged bed rest.

**Immune Responses.** The immune system also is subject to physiologic changes associated with bed rest including an increase in IL-1, IL-6, and TNF-α production. An increase in these mediators has been associated with hyperinflammatory reactions and tissue injury. Increased IL-1 production contributes to the bone and mineral loss that occurs during bed rest.

**Gastrointestinal Responses**
Gastrointestinal responses to bed rest vary. Loss of appetite, slowed rate of absorption, and distaste for food combine to contribute to nutritional hypoproteinemias. Passage of food through the gastrointestinal tract is slowed when the person is placed in the supine position. In a supine position the velocity of peristalsis decreases by 60%. Also, the loss of plasma volume and dehydration can combine to exacerbate gastrointestinal problems. Thus, constipation and fecal impaction are frequent complications that occur when people experience prolonged periods of immobility and bed rest. With inactivity, there is slowed movement of feces through the colon. The act of defecation requires the integration of the abdominal muscles, the diaphragm, and the levator ani. Muscle atrophy and loss of tone occur in the immobilized person and interfere with the normal act of defecation.

**Sensory Responses**
Bed rest and immobility reduce the quality and quantity of sensory information available from kinesthetic, visual, auditory, and tactile sensation. It also reduces the person’s ability to interact with the environment and contributes to impaired sensory responses. Common occurrences include impaired sense of motion and limb movement, visual and auditory hallucinations, vivid dreams, inefficient thought processes, loss of contact with reality, and alteration in tactile stimulation.

In addition to sensory deprivation related to prolonged bed rest and immobility, persons may experience a sensory monotony from the hospital environment. Repetitious and meaningless sounds from cardiac monitors, respirators, and hospital personnel, along with an environment that may be void of a normal day–night cycle, also contribute to impaired sensory perception.

**Skin Responses**
Except for the soles of the feet, the skin is not designed for weight bearing. However, during bed rest, the large surface area of the skin bears weight and is in constant contact with the surface of the bed. Constant pressure is transmitted to the skin, subcutaneous tissue, and muscle, especially to those tissues over bony prominences. This constant contact causes increased pressure and impairs normal capillary blood flow, which interferes with the exchange of nutrients and waste products. Tissue ischemia and necrosis may result and lead to the development of pressure ulcers.

**Time Course of Physiologic Responses**
The deconditioning responses to the inactivity of immobility and bed rest affect all body systems. One of the important factors to keep in mind is the rapidity with which the changes occur and the length of time required to overcome these effects. The body responds in a characteristic pattern to the effects of the supine position and bed rest. During the first 3 days of bed rest, one of the first changes to occur is a massive diuresis. Accompanying the diuresis are increases in serum osmolality, hematocrit, venous compliance, and urinary sodium and chloride excretion. Fluid losses stabilize by approximately the 4th day. By days 4 to 7, there are changes in the hemolytic system. Fibrinogen and fibrinolytic activity increase, and clotting time is prolonged. The cardiovascular system responds with a decrease in cardiac output and stroke volume. The metabolic rate decreases the longer one is experiencing bed rest.

Additional effects on the hemolytic system are observed on days 8 to 14. Red blood cell number is decreased, and the phagocytic ability of leukocytes is reduced. There is a decrease in lean body mass, and after 15 days of bed rest, osteoporosis and hypercalciuria occur.

**Psychosocial Responses**
Immunity often sets the stage for changes in the person’s response to illness. People adapt to prolonged bed rest and immobility through a series of physiologic responses and through changes in affect, perception, and cognition. Affective changes include increased anxiety, fear, depression, hostility, rapid mood changes, and alterations in normal sleep patterns. These changes in mood occur with hospitalized people who are subjected to periods of prolonged bed rest and immobility and in people in confinement, such as astronauts and prisoners. Research on immobilized or isolated people has demonstrated that the motivation to learn decreases with periods of prolonged immobility, as does the ability to learn and retain new material and transfer newly learned material to a different situation.

**Management of People Who Are Immobile or on Bed Rest**
A holistic approach should be taken when caring for people who are immobile or require prolonged periods of bed rest. Interventions and treatment should include actions that address the person’s physical and psychosocial needs. The goals of care for the immobilized person include structuring a safe environment in which the person is not at risk for complications, providing diversional activities to offset problems with sensory deprivation, and preventing complications of bed rest by implementing an interdisciplinary plan of care that includes repositioning schedules, prophylactic interventions to prevent DVT, and consultation with various disciplines to provide a comprehensive approach to care and treatment.
IN SUMMARY

During the last 75 years, the use of bed rest has undergone a complete reversal as a standard of treatment for a variety of medical conditions. Over time, research findings have described the deleterious consequences of inactivity. All body systems are affected by complications of immobility and prolonged bed rest.

The responses to bed rest and immobility affect all body systems. One of the important factors is the rapidity with which the changes occur and the long time required to overcome the effects of prolonged bed rest and immobility. Adverse effects of prolonged immobility and bed rest include a decreased cardiac output, orthostatic intolerance, dehydration, and sensory deprivation, as well as the potential for development of thrombophlebitis, pneumonia, kidney stones, and pressure ulcers.

REVIEW EXERCISES

1. A 60-year-old man sustains an acute myocardial infarction. He has been discharged from the hospital and is about to enter a cardiac rehabilitation program. On his first day of the program, he is being examined for his tolerance to the exercise program. 
   A. One of the tests that he is scheduled to undergo is the treadmill stress test. How will this test contribute to the evaluation of his ability to engage in exercise? 
   B. What other subjective tests might be used to determine his exercise tolerance?

2. A 40-year-old woman who is being treated with chemotherapy for breast cancer complains of excessive fatigue and activity intolerance. She claims she has so little energy she can hardly get up in the morning and has difficulty concentrating and doing such simple activities as shopping. 
   A. What are some of the possible explanations for this woman’s excessive fatigue? 
   B. What types of medical tests might be done to identify possible causes of fatigue? 
   C. What types of treatment might be used to alleviate some of her symptoms?

3. A 23-year-old man, who has sustained multiple fractures and contusions in a motorcycle accident, is confined to bed rest in the supine position. He has been on bed rest for 2 days and has lost about 500 mL of extracellular fluid volume because of diuresis.

A. Explain the physiologic rationale for the excessive diuresis.
B. Identify two complications of bed rest that might occur as the result of this loss of extracellular fluid volume.
C. Upon getting out of bed on the 4th day, he suddenly turns pale, has an increase in heart rate, and complains of dizziness. What has happened to this man?

Sue Roon, 19 years old, presented at her primary care provider’s office with a swollen left ankle about twice the ankle’s normal size. She explains that she has had this same swelling occur spontaneously without injury or trauma about five times over the last 18 months. The swelling usually lasts approximately 36 hours and then resolves on its own. Her primary care provider has had it x-rayed, and it shows no fracture or abnormal findings. She also shares that her right wrist has swelled up similarly about three times over the last 18 months (spontaneously without any injury). She generally takes two tablets of Advil, applies ice, uses a compression bandage, and tries to forget about it, and the swelling goes away.

She explains that, in addition to the unusual swelling, she has started to feel more tired than usual. She can think of no reason for this given she has not had any strenuous activity or stress lately. She also reports a slight headache that comes and goes and just began again about 2 days ago when the latest swelling began. Her vital signs are all normal but she has a temperature of 100.2°F. She has no other complaints and perceives herself to be in “good health.” She has no family history of autoimmune disorders such as Sjögren syndrome or rheumatoid arthritis. She also has no personal history of any neurological or muscle disorders or current muscle discomfort or tenderness at the fibromyalgia classic anatomical sites, so she is not experiencing a flare-up of fibromyalgia. She states she does do a good amount of hiking and gardening but denies being bitten by a tick. She says she did not have any skin rash or feel that any insects had bitten her over the last 2 years. However, because she lives in NJ (which is a high-risk area for infection with Lyme disease) and she spends a lot of time outdoors, her primary care provider decides she should be worked up for Lyme disease (Borrelia burgdorferi). A complete blood count (CBC) with differential, sedimentation rate, and Lyme enzyme immunoassay come back positive. She then is retested with a Western blot test, which is also positive for B. burgdorferi reactive antibodies. She is diagnosed with Lyme disease and given doxycycline 100 mg BID for 1 month. Her primary care provider refers her to an infectious disease physician since it is thought she may have had Lyme disease for 18 months. Ms. Roon’s case is discussed further in this chapter.
All living creatures share two basic objectives in life: survival and reproduction. This doctrine applies equally to all members of the living world, including bacteria, viruses, fungi, and protozoa. To satisfy these goals, organisms must extract from the environment essential nutrients for growth and proliferation. For countless microscopic organisms, that environment includes the human body. Table 12.1 illustrates common pathogens that invade humans. Normally, the contact between humans and microorganisms is incidental and, in certain situations, may actually benefit both organisms. Under extraordinary circumstances, however, the invasion of the human body by microorganisms can produce harmful and potentially lethal consequences. The consequences of these invasions are collectively called infectious diseases.
Occasionally, infection and colonization are used interchangeably. However, the term infection describes the presence and multiplication within a host of another living organism, with subsequent injury to the host, whereas colonization describes the act of establishing a presence, a step required in the multifaceted process of infection.

One common misconception should be dispelled from the start: not all interactions between microorganisms and humans are detrimental. The internal and external exposed surfaces of the human body are normally and harmlessly inhabited by a multitude of bacteria, collectively referred to as the normal microflora. Although the colonizing bacteria acquire nutritional needs and shelter, the host is not adversely affected by the relationship. An interaction such as this is called commensalism, and the colonizing microorganisms are sometimes referred to as commensal flora. The term mutualism is applied to an interaction in which the microorganism and the host both derive benefits from the interaction. For example, certain inhabitants of the human intestinal tract extract nutrients from the host and secrete essential vitamin by-products of metabolism (e.g., vitamin K) that are absorbed and used by the host. A parasitic relationship is one in which only the infecting organism benefits from the relationship and the host either gains nothing from the relationship or sustains injury from the interaction. If the host sustains injury or pathologic damage in response to a parasitic infection, the process is called an infectious disease.

The severity of an infectious disease can range from mild to life threatening. Severity depends on many variables, including the health of the host at the time of infection and the virulence (disease-producing potential) of the microorganism. A select group of microorganisms called pathogens are so virulent that they are rarely found in the absence of disease. Fortunately, there are few human pathogens in the microbial world. Most microorganisms are harmless saprophytes, free-living organisms obtaining their growth from dead or decaying organic material in the environment. All microorganisms, even saprophytes and members of the normal flora, can be opportunistic pathogens, capable of producing an infectious disease when the health and immunity of the host have been severely weakened by illness, malnutrition, or medical therapy.
scrapie prion proteins (called PrPSC) are actually altered or mutated forms of a normal host protein called cellular PrP C.2 Differences in the posttranslational structure cause the two forms to behave differently. The PrPSC is resistant to the action of proteases (enzymes that degrade excess or deformed proteins) and aggregates in the cytoplasm of affected neurons as amyloid fibrils. The normal PrP C is protease sensitive and appears on the cell surface.

Prion diseases present significant challenges for management due to the pathogenic structure of PrPSC. It is very stable and, therefore, is resistant to many antibiotics. Studies investigating transmission of prion diseases in animals clearly demonstrate that prions replicate, leading researchers to investigate how proteins can reproduce in the absence of genetic material.1 Based on current models, it is believed that PrPSC binds to the normal PrP C on the cell surface, causing it to be processed into PrPSc, which is released from the cell and then aggregates into amyloid-like plaques in the brain. The cell then replenishes the PrP C and the cycle continues. As PrPSc accumulates, it spreads within the axons of the nerve cells, causing progressively greater damage of host neurons and the eventual incapacitation of the host. Prions lack reproductive and metabolic functions, so the currently available antimicrobial agents are useless against them.

Viruses
Viruses are the smallest obligate intracellular pathogens. They have no organized cellular structures but instead consist of a protein coat, or capsid, surrounding a nucleic acid core, or genome, of RNA or DNA—never both (Fig. 12.2). Some viruses are enclosed within a lipoprotein envelope derived from the cytoplasmic membrane of the parasitized host cell. Enveloped viruses include members of the herpesvirus group and paramyxoviruses (e.g., influenza and poxviruses). Certain enveloped viruses are continuously shed from the infected cell surface enveloped in buds pinched from the cell membrane.

The viruses of humans and animals have been categorized somewhat arbitrarily according to various characteristics. These include the type of viral genome (single-stranded or double-stranded DNA or RNA), physical characteristics (e.g., size, presence or absence of a membrane envelope), the mechanism of replication (e.g., retroviruses), the mode of transmission (e.g., arthropod-borne viruses, enteroviruses), target tissue, and the type of disease produced (e.g., hepatitis A, B, C, D, and E viruses), to name just a few.

Viruses are incapable of replication outside of a living cell. They must penetrate a susceptible living cell and use the viral genome to direct the production and assembly of new viral particles within the host cell. The resulting virions are then released from the cell, either by budding at the cell surface or by rupture of the cell membrane. The host cell is then no longer able to function and usually undergoes death, which is what it means to be infected.

Prions No Unknown 55 kDa E −
Viruses No DNA or RNA 0.02–0.3 I/E −
Bacteria No DNA 0.5–15 E ±
Mycoplasmas No DNA 0.2–0.3 E −
Spirochetes No DNA 6–15 E +
Rickettsiae No DNA 0.2–2 I −
Chlamydiae No DNA 0.3–1 I −
Yeast Yes DNA 2–60 I/E −
Molds Yes DNA 2–15 E −
Protozoans Yes DNA 1–60 I/E +
Helminths Yes DNA 2 mm to >1 m E +

*Micrometers unless indicated.

### Agents of Infectious Disease

The agents of infectious disease include prions, viruses, bacteria, Rickettsiae and Chlamydiae, fungi, and parasites. A summary of the salient characteristics of these human microbial pathogens is presented in Table 12.2.
biosynthetic structure of the cell to produce viral progeny. The process of viral replication is shown in Figure 12.3. Not every viral agent causes lysis and death of the host cell during the course of replication. Some viruses enter the host cell and insert their genome into the host cell chromosome, where it remains in a latent, nonreplicating state for long periods without causing disease. Under the appropriate stimulation, the virus undergoes active replication and produces symptoms of disease months to years later. Members of the herpesvirus group and adenovirus are examples of latent viruses. Herpesviruses include the viral agents of chickenpox and zoster (varicella–zoster), cold sores (herpes simplex virus [HSV] type 1), genital herpes (HSV type 2), cytomegalovirus infections, roseola (human herpesvirus 6), infectious
mononucleosis (IM) (Epstein-Barr virus [EBV]) (see Fig. 12.4), and Kaposi sarcoma (herpesvirus 8). The resumption of the latent viral replication may produce symptoms of primary disease (e.g., genital herpes) or cause an entirely different symptomatology (e.g., shingles instead of chickenpox).

A family of viruses that has gained a great deal of attention is the Orthomyxoviridae or flu viruses. There has been attention focused on the H5N1 variant, commonly known as the avian influenza virus, and the H1N1 variant, commonly known as swine flu. The avian influenza viruses differ from the usual human influenza viruses by the hosts they normally infect. Avian influenza viruses typically infect wild birds. However, on occasion a new virus may result from genetic rearrangements that make it better fit to infect humans. When this occurs, the human population is more susceptible because the virus is unfamiliar to most of our immune systems. The H1N1 or swine flu was most notable in 2009. This influenza A virus was susceptible to oseltamivir (Tamiflu), but resistant to amantadine. Rapid influenza diagnostic tests (RITs) have been developed to diagnose a person with H1N1 and other influenza viruses.

Since the early 1980s, members of the retrovirus group have received considerable attention after identification of the human immunodeficiency viruses (HIV) as the causative agent of acquired immunodeficiency syndrome (AIDS). The retroviruses have a unique mechanism of replication. After entry into the host cell, the viral RNA genome is first translated into DNA by a viral enzyme called reverse transcriptase. The viral DNA copy is then integrated into the host chromosome where it exists in a latent state, similar to the herpesviruses. Reactivation and replication require a reversal of the entire process. Some retroviruses lyse the host cell during the process of replication. In the case of HIV, the infected cells regulate the immunologic defense system of the host, and their lysis leads to a permanent suppression of the immune response.

In addition to causing infectious diseases, certain viruses also have the ability to transform normal host cells into malignant cells during the replication cycle. This group of viruses is referred to as oncogenic and includes certain retroviruses and DNA viruses, such as the herpesviruses, adenoviruses, and papovaviruses. Human papillomaviruses (HPVs), members of the papovavirus family, cause cutaneous and genital warts, and several genotypes are associated with cervical cancer. The first vaccine (Gardasil) to prevent cervical cancer, precancerous genital lesions, genital warts, and anal and oropharyngeal cancers due to HPV types 6, 11, 16, and 18 was developed in 2006.

**Bacteria**

Bacteria are autonomously replicating unicellular organisms known as *prokaryotes* because they lack an organized nucleus. Compared with nucleated eukaryotic cells, the bacterial cell is small and structurally relatively primitive. Similar to eukaryotic cells, but unlike viruses, bacteria contain both DNA and RNA. They are the smallest of all living cells and range from 0.1 to 10 \( \mu \text{m} \). They contain no organized intracellular organelles, and the genome consists of only a single chromosome of DNA. Many bacteria transiently harbor smaller extrachromosomal pieces of circular DNA called plasmids. Occasionally, plasmids contain genetic information that increases the virulence or antibiotic resistance of the organism.

The prokaryotic cell is organized into an internal compartment called the *cytoplasm*, which contains the reproductive and metabolic machinery of the cell. The cytoplasm is surrounded by a flexible lipid membrane, called the *cytoplasmic membrane*. This in turn is enclosed within a rigid cell wall. The structure and synthesis of the cell wall determine the microscopic shape of the bacterium (e.g., spherical [cocci], helical [spirilla], or elongate [bacilli]). Most bacteria produce...
Figure 12.4 • Role of Epstein-Barr virus (EBV) in infectious mononucleosis (IM), nasopharyngeal carcinoma, and Burkitt lymphoma. EBV invades and replicates within the salivary glands or pharyngeal epithelium and is shed into the saliva and respiratory secretions. Additionally, in some people the virus transforms pharyngeal epithelial cells, which then can cause nasopharyngeal carcinoma. Then in some people who are not immune from childhood exposure, EBV can cause IM. EBV can infect B lymphocytes and stimulate the production of atypical lymphocytes, which kill virally infected B cells and suppress immunoglobulin production. Some infected B cells can transform into malignant lymphocytes of Burkitt lymphoma. (From Rubin R., Strayer D. (Eds.) (2012). *Rubin’s pathology: Clinicopathologic foundations of medicine* (6th ed., p. 344). Philadelphia, PA: Lippincott Williams & Wilkins.)
a cell wall composed of a distinctive polymer known as peptidoglycan. This polymer is produced only by prokaryotes and is therefore an attractive target for antibacterial therapy. Several bacteria synthesize an extracellular capsule composed of protein or carbohydrate. The capsule protects the organism from environmental hazards such as the immunologic defenses of the host.

Certain bacteria are motile as the result of external whiplike appendages called flagella. The flagella rotate like a propeller, transporting the organism through a liquid environment. Bacteria can also produce hairlike structures projecting from the cell surface called pili or fimbriae, which enable the organism to adhere to surfaces such as mucous membranes or other bacteria.

Most prokaryotes reproduce asexually by simple cellular division. The manner in which an organism divides can influence the microscopic morphology. For instance, when the cocci divide in chains, they are called streptococci; in pairs, diplococci; and in clusters, staphylococci. The growth rate of bacteria varies significantly among different species and depends greatly on physical growth conditions and the availability of nutrients. In the laboratory, a single bacterium placed in a suitable growth environment, such as an agar plate, reproduces to the extent that it forms a visible colony composed of millions of bacteria within a few hours (Fig. 12.5).

In nature, however, bacteria rarely exist as single cells floating in an aqueous environment. Rather, bacteria prefer to stick to and colonize environmental surfaces, producing structured communities called biofilms. The organization and structure of biofilms permit access to available nutrients and elimination of metabolic waste. Within the biofilm, individual organisms use chemical signaling as a form of primitive intercellular communication to represent the state of the environment. These signals inform members of the community when sufficient nutrients are available for proliferation or when environmental conditions warrant dormancy or evacuation. Examples of biofilms abound in nature and are found on surfaces of aquatic environments and on humans. Eighty percent of all chronic infections are due to the presence of biofilms.

The physical appearance of a colony of bacteria grown on an agar plate can be quite distinctive for different species. Bacteria are also identified according to how they divide. Some bacteria produce pigments that give colonies a unique color; some produce highly resistant spores when faced with an unfavorable environment. The spores can exist in a quiescent state almost indefinitely until suitable growth conditions are encountered, at which time the spores germinate and the organism resumes normal metabolism and replication.

Bacteria are extremely adaptable life forms. They are found not just in humans and other hosts but in almost every environmental extreme on earth. However, each individual bacterial species has a well-defined set of growth parameters, including nutrition, temperature, light, humidity, and atmosphere. Bacteria with extremely strict growth requirements are called fastidious. For example, Neisseria gonorrhoeae, the bacterium that causes gonorrhea, cannot live for extended periods outside the human body. Some bacteria require oxygen for growth and metabolism and are called aerobes. Others cannot survive in an oxygen-containing environment and are called anaerobes. An organism capable of adapting its metabolism to aerobic or anaerobic conditions is called facultatively anaerobic.

In the laboratory, bacteria are generally classified according to the microscopic appearance and staining properties of the cell. The Gram stain is the most widely used staining procedure. Bacteria are designated as gram-positive organisms if they are stained purple by a primary basic dye (usually crystal violet). Those that are not stained by the crystal violet but are counterstained red by a second dye (safranin) are called gram-negative organisms. Staining characteristics and microscopic morphology are used in combination to describe bacteria. For example, Streptococcus pyogenes, the agent of scarlet fever and rheumatic fever, is a gram-positive streptococcal organism.
that is spherical, grows in chains, and stains purple by Gram stain. *Legionella pneumophila*, the bacterium responsible for Legionnaire disease, is a gram-negative rod.

Another means of classifying bacteria according to microscopic staining properties is the acid-fast stain. Because of their unique cell membrane fatty acid content and composition, certain bacteria are resistant to the decolorization of a primary stain (either carbol fuschin or a combination of auramine and rhodamine) when treated with a solution of acid alcohol. These organisms are termed acid-fast and include a number of significant human pathogens, most notably *Mycobacterium tuberculosis* and other mycobacteria.²

For purposes of taxonomy (i.e., identification and classification), each member of the bacterial kingdom is categorized into a small group of biochemically and genetically related organisms called the genus and further subdivided into distinct individuals within the genus called species. The genus and species assignment of the organism is reflected in its name (e.g., *Staphylococcus* [genus] *aureus* [species]).

**Spirochetes.** The *spirochetes* are an eccentric category of bacteria that are mentioned separately because of their unusual cellular morphology and distinctive mechanism of motility. Technically, the spirochetes are gram-negative rods but are unique in that the cell’s shape is helical and the length of the organism is many times its width. A series of filaments are wound about the cell wall and extend the entire length of the organism is many times its width. A series of filaments propel the organism through an aqueous environment in a corkscrew motion.

Spirochetes are anaerobic organisms and comprise three genera: *Leptospira*, *Borrelia*, and *Treponema*. Each genus has saprophytic and pathogenic strains. The pathogenic leptospires infect a wide variety of wild and domestic animals. Infected animals shed the organisms into the environment through the urinary tract. Transmission to humans occurs by contact with infected animals or urine-contaminated surroundings. Leptospires gain access to the host directly through mucous membranes or breaks in the skin and can produce a severe and potentially fatal illness called *Weil syndrome*. In contrast, the borreliae are transmitted from infected animals to humans through the bite of an arthropod vector such as lice or ticks. Included in the genus *Borrelia* are the agents of relapsing fever (*Borrelia recurrentis*) and Lyme disease (*B. burgdorferi*).

Pathogenic *Treponema* species require no intermediates and are spread from person to person by direct contact. The most important member of the genus is *Treponema pallidum*, the causative agent of syphilis.

**Mycoplasmas.** The mycoplasmas are unicellular prokaryotes capable of independent replication. These organisms are less than one third the size of bacteria at approximately 0.3 μm at their largest diameter and contain a small DNA genome approximately one half the size of the bacterial chromosome. The cell is composed of cytoplasm surrounded by a membrane but, unlike bacteria, the mycoplasmas do not produce a rigid peptidoglycan cell wall. As a consequence, the microscopic appearance of the cell is highly variable, ranging from coccoid forms to filaments, and the mycoplasmas are resistant to cell-wall–inhibiting antibiotics, such as penicillins and cephalosporins.

The mycoplasmas affecting humans are divided into three genera: *Mycoplasma*, *Ureaplasma*, and *Acholeplasma*. The first two require cholesterol from the environment to produce the cell membrane; the acholeplasmas do not. In the human host, mycoplasmas are commensals. However, a number of species are capable of producing serious diseases, including pneumonia (*Mycoplasma pneumoniae*), genital infections (*Mycoplasma hominis* and *Ureaplasma urealyticum*), and maternally transmitted respiratory infections to infants with low birth weight (*U. urealyticum*).²,³

**Rickettsiaceae, Anaplasmataceae, Chlamydiaceae, and Coxiella**

This interesting group of organisms combines the characteristics of viral and bacterial agents to produce disease in humans. All are obligate intracellular pathogens, like the viruses, but produce a rigid peptidoglycan cell wall, reproduce asexually by cellular division, and contain RNA and DNA, similar to the bacteria.²

The *Rickettsiaceae* depend on the host cell for essential vitamins and nutrients, but the *Chlamydiaceae* appear to scavenge intermediates of energy metabolism such as adenosine triphosphate (ATP). The *Rickettsiaceae* infect but do
not produce disease in the cells of certain arthropods such as fleas, ticks, and lice. The organisms are accidentally transmitted to humans through the bite of the arthropod (i.e., the vector) and produce a number of potentially lethal diseases, including Rocky Mountain spotted fever and epidemic typhus. Rocky Mountain spotted fever is a reportable disease that has increased in frequency over the last decade from two cases in 1 million people to eight cases in 1 million people. However, the death rate has decreased to approximately 0.5%.

The Chlamydiaceae are slightly smaller than the Rickettsiaceae but are structurally similar and are transmitted directly between susceptible vertebrates without an intermediate arthropod host. Transmission and replication of Chlamydiaceae occur through a defined life cycle. The infectious form, called an elementary body, attaches to and enters the host cell, where it transforms into a larger reticulate body. This undergoes active replication into multiple elementary bodies, which are then shed into the extracellular environment to initiate another infectious cycle. Chlamydial diseases of humans include sexually transmitted genital infections (Chlamydia trachomatis), which are the most common of the bacterial sexually transmitted infections (STIs); ocular infections and pneumonia of newborns (Chlamydia pneumoniae); upper respiratory tract infections in children, adolescents, and young adults (Chlamydia phila pneumoniae), which generally does not cause severe disease unless there is an underlying pulmonary disorder; and respiratory disease acquired from infected birds (Chlamydia psittaci).

Organisms within the family Anaplasmataceae (including the reorganized genera Ehrlichia, Anaplasma, Neorickettsia, and Wolbachia) are also obligate intracellular organisms that resemble the Rickettsiaceae in structure and produce a variety of veterinary and human diseases, some of which have a tick vector. These organisms target host mononuclear and polymorphonuclear white blood cells for infection and, similar to the Chlamydiaceae, multiply in the cytoplasm of infected leukocytes within vacuoles called murulae. Unlike the Chlamydiaceae, however, the Anaplasmataceae do not have a defined life cycle and are independent of the host cell for energy production. Ehrlichia sennetsu, which is primarily restricted to Japan, produces a disease called sennetsu fever that resembles IM. Disease caused by this organism differs from other Anaplasmataceae because it is associated with eating raw fish infected with E. sennetsu–infected parasites. The most common infections caused by Anaplasmataceae are human monocytic and granulocytic ehrlichiosis. Human monocytic ehrlichiosis is a disease caused by Ehrlichia chaffeensis and E. canis that can easily be confused with Rocky Mountain spotted fever.

Clinical disease severity ranges from mild to life-threatening. Manifestations include generalized malaise, anorexia and nausea, fever, and headache. Decreases in white blood cells (leukopenia) and platelets (thrombocytopenia) often occur. Severe sequelae include severe respiratory failure, encephalopathy, and acute renal failure. The disease is usually more severe in older adults and people with compromised immune function. Evidence validates the importance of empirical antibiotic treatment when one suspects ehrlichiosis since a fulminant and life-threatening infection is likely with immunocompromised people. Human granulocytic ehrlichiosis, which is caused by two species (Anaplasma phagocytophilum and Ehrlichia ewingii), is also transmitted by ticks. The symptoms are similar to those seen with human monocytophagic ehrlichiosis.

The genus Coxiella contains only one species, C. burnetii. Like its rickettsial counterparts, it is a gram-negative intracellular organism that infects a variety of animals, including cattle, sheep, and goats. In humans, Coxiella infection produces a disease called Q fever, characterized by a nonspecific febrile illness often accompanied by headache, chills, and mild pneumonia-like symptoms. The organism produces a highly resistant sporelike stage that is transmitted to humans when contaminated animal tissue is aerosolized (e.g., during meat processing) or by ingestion of contaminated milk.

**Fungi**

The fungi are free-living, eukaryotic saprophytes found in every habitat on earth. Some are members of the normal human microflora. Fortunately, few fungi are capable of causing diseases in humans, and most of these are incidental, self-limited infections of skin and subcutaneous tissue. Serious fungal infections are rare and usually initiated through puncture wounds or inhalation. Despite their normally harmless nature, fungi can cause life-threatening opportunistic diseases when host defense capabilities have been disabled.

The fungi can be separated into two groups, yeasts and molds, based on rudimentary differences in their morphology. The yeasts are single-celled organisms, approximately the size of red blood cells, which reproduce by a budding process. The buds separate from the parent cell and mature into identical daughter cells. Molds produce long, hollow, branching filaments called hyphae. Some molds produce cross walls, which segregate the hyphae into compartments, and others do not. A limited number of fungi are capable of growing as yeasts at one temperature and as molds at another. These organisms are called dimorphic fungi and include a number of human pathogens such as the agents of blastomycosis (Blastomyces dermatitidis), histoplasmosis (Histoplasma capsulatum), and coccidioidomycosis (Coccidioides immitis).

The appearance of a fungal colony tends to reflect its cellular composition. Colonies of yeast are generally smooth with a waxy or creamy texture. molds tend to produce cottony or powdery colonies composed of mats of hyphae collectively called a mycelium. The mycelium can penetrate the growth surface or project above the colony like the roots and branches of a tree. Yeasts and molds produce a rigid cell wall layer that is chemically unrelated to the peptidoglycan of bacteria and is therefore not susceptible to the effects of penicillin-like antibiotics.

Most fungi are capable of sexual or asexual reproduction. The former process involves the fusion of zygotes with the production of a recombinant zygospore. Asexual reproduction involves the formation of highly resistant spores called conidia or sporangiospores, which are borne by specialized
structures that arise from the hyphae. Molds are identified in the laboratory by the characteristic microscopic appearance of the asexual fruiting structures and spores.

Like the bacterial pathogens of humans, fungi can produce disease in the human host only if they can grow at the temperature of the infected body site. For example, a number of fungal pathogens called dermatophytes are incapable of growing at core body temperature (37°C), and the infection is limited to the cooler cutaneous surfaces. Diseases caused by these organisms, including ringworm, athlete’s foot, and jock itch, are collectively called superficial mycoses. Systemic mycoses are serious fungal infections of deep tissues and, by definition, are caused by organisms capable of growth at 37°C. Yeasts such as Candida albicans are commensal flora of the skin, mucous membranes, and gastrointestinal tract and are capable of growth at a wider range of temperatures. Intact immune mechanisms and competition for nutrients provided by the bacterial flora normally keep colonizing fungi in check. Alterations in either of these components by disease states or antibiotic therapy can upset the balance, permitting fungal overgrowth and setting the stage for opportunistic infections.

**Parasites**

In a strict sense, any organism that derives benefits from its biologic relationship with another organism is a parasite. In the study of clinical microbiology, however, the term parasite has evolved to designate members of the animal kingdom that infect and cause disease in other animals, and includes protozoa, helminths, and arthropods.

The protozoa are unicellular animals with a complete complement of eukaryotic cellular machinery, including a well-defined nucleus and organelles. Reproduction may be sexual or asexual, and life cycles may be simple or complicated, with several maturation stages requiring more than one host for completion. Most are saprophytes, but a few have adapted to the accommodations of the human environment and produce a variety of diseases, including malaria, amebic dysentery, and giardiasis. Protozoan infections can be passed directly from host to host such as through sexual contact, indirectly through contaminated water or food, or by way of an arthropod vector. Direct or indirect transmission results from the ingestion of highly resistant cysts or spores that are shed in the feces of an infected host. When the cysts reach the intestine, they mature into vegetative forms called trophozoites, which are capable of asexual reproduction or cyst formation. Most trophozoites are motile by means of flagella, cilia, or ameboid motion.

The helminths are a collection of wormlike parasites that include the nematodes or roundworms, cestodes or tapeworms, and trematodes or flukes. The helminths reproduce sexually within the definitive host, and some require an intermediate host for the development and maturation of offspring. Humans can serve as the definitive or intermediate host and, in certain diseases such as trichinosis, as both. Transmission of helminth diseases occurs primarily through the ingestion of fertilized eggs (ova) or the penetration of infectious larval stages through the skin—directly or with the aid of an arthropod vector. Helminth infections can involve many organ systems and sites, including the liver and lung, urinary and intestinal tracts, circulatory and central nervous systems, and muscle. Although most helminth diseases have been eradicated from the United States, they are still a major health concern of developing nations.

The parasitic arthropods of humans and animals include the vectors of infectious diseases (e.g., ticks, mosquitoes, biting flies) and the ectoparasites. The ectoparasites infest external body surfaces and cause localized tissue damage or inflammation secondary to the bite or burrowing action of the arthropod. The most prominent human ectoparasites are mites (scabies), chiggers, lice (head, body, and pubic), and fleas. Transmission of ectoparasites occurs directly by contact with immature or mature forms of the arthropod or its eggs found on the infested host or the host’s clothing, bedding, or grooming articles such as combs and brushes. Many of the ectoparasites are vectors of other infectious diseases, including endemic typhus and bubonic plague (fleas) and epidemic typhus (lice).

### IN SUMMARY

Throughout life, humans are continuously and harmlessly exposed to and colonized by a multitude of microscopic organisms. This relationship is kept in check by the intact defense mechanisms of the host (e.g., mucosal and cutaneous barriers, normal immune function) and the innocuous nature of most environmental microorganisms. Those factors that weaken the host’s resistance or increase the virulence of colonizing microorganisms can disturb the equilibrium of the relationship and cause disease. The degree to which the balance is shifted in favor of the microorganism determines the severity of illness.

There is an extreme diversity of prokaryotic and eukaryotic microorganisms capable of causing infectious diseases in humans. With the advent of immnosuppressive medical therapy and immunosuppressive diseases such as AIDS, the number and type of potential microbial pathogens, the so-called opportunistic pathogens, have increased dramatically. However, most infectious illnesses in humans continue to be caused by only a small fraction of the organisms that compose the microscopic world.

### MECHANISMS OF INFECTION

After completing this section of the chapter, you should be able to meet the following objectives:

- Describe the stages of an infectious disease after the potential pathogen has entered the body.
- List the systemic manifestations of infectious disease.
Epidemiology of Infectious Diseases

Epidemiology is the study of factors, events, and circumstances that influence the transmission of infectious diseases among humans. The ultimate goal of the epidemiologist is to devise strategies that interrupt or eliminate the spread of an infectious agent. To accomplish this, infectious diseases must be classified according to incidence, portal of entry, source, symptoms, disease course, site of infection, and virulence factors so that potential outbreaks may be predicted and averted or appropriately treated.

Epidemiology is a science of rates and statistics. The expected frequency of any infectious disease must be calculated so that gradual or abrupt changes in frequency can be observed. The term incidence is used to describe the number of new cases of an infectious disease that occur within a defined population (e.g., per 100,000 people) over an established period of time (e.g., monthly, quarterly, yearly). Disease prevalence indicates the number of active cases at any given time. A disease is considered endemic in a particular geographic region if the incidence and prevalence are expected and relatively stable. An epidemic describes an abrupt and unexpected increase in the incidence of disease over endemic rates. A pandemic refers to the spread of disease beyond continental boundaries. The advent of rapid worldwide travel increased the likelihood of pandemic transmission of pathogenic microorganisms.

As an illustration of these principles, an outbreak of a suspected respiratory viral illness—subsequently identified as severe acute respiratory syndrome (SARS)—was recognized in the Guangdong province in southern China beginning in November 2002. The illness was highly transmissible, as evidenced by the first recognized occurrence in Taiwan. Four days after returning to Taiwan from work in the Guangdong province, a businessman developed a febrile illness and was admitted to a local hospital. Within 1 month, a large nosocomial outbreak of SARS was documented to have affected approximately 3000 people in Taipei City, Taiwan. Once the SARS outbreak had crossed continental borders for the first time, its classification was changed from an epidemic to a pandemic.

Portal of Entry

The portal of entry refers to the process by which a pathogen enters the body, gains access to susceptible tissues, and causes disease. Among the potential modes of transmission are penetration, direct contact, ingestion, and inhalation. The portal of entry does not dictate the site of infection. Ingested pathogens may penetrate the intestinal mucosa, disseminate through the circulatory system, and cause diseases in other organs such as the lung or liver. Whatever the mechanisms of entry, the transmission of infectious agents is directly related to the number of infectious agents absorbed by the host.

Penetration

Any disruption in the integrity of the body’s surface barrier—skin or mucous membranes—is a potential site for invasion of microorganisms. The break may be the result of an accidental injury causing abrasions, burns, or penetrating wounds; medical procedures such as surgery or catheterization; or a primary infectious process that produces surface lesions such as chickenpox or impetigo. Direct inoculation from intravenous drug use or an animal or arthropod bite also can occur.

Direct Contact

Some pathogens are transmitted directly from infected tissue or secretions to exposed, intact mucous membranes. This is especially true of certain STIs, such as gonorrhea, syphilis, chlamydia, and genital herpes, for which exposure of uninfected membranes to pathogens occurs during intimate contact.

The transmission of STIs is not limited to sexual contact. Vertical transmission of these agents, from mother to child, can occur across the placenta or during birth when the mucous membranes of the child come in contact with infected vaginal secretions of the mother. When an infectious disease is transmitted from mother to child during gestation or birth, it is classified as a congenital infection. The most frequently observed congenital infections include toxoplasmosis (caused by the parasite *Toxoplasma gondii*), syphilis, rubella, cytomegalovirus infection, and HSV infections (the TORCH infections); varicella–zoster (chickenpox); parvovirus B19; group B streptococci (*Streptococcus agalactiae*); and HIV. Of these, cytomegalovirus is by far the most common cause of congenital infection in the United States.

The severity of congenital defects associated with these infections depends greatly on the gestational age of the fetus when transmission occurs, but most of these agents can cause profound mental retardation and neurosensory deficits, including blindness and hearing loss. HIV rarely produces overt signs and symptoms in the infected newborn, and it sometimes takes years for the effects of the illness to manifest.

Ingestion

The entry of pathogenic microorganisms or their toxic products through the oral cavity and gastrointestinal tract represents one of the more efficient means of disease transmission in humans. Many bacterial, viral, and parasitic infections, including cholera, typhoid fever, dysentery (amebic and bacillary), food poisoning, traveler’s diarrhea, cryptosporidiosis, and hepatitis A, are initiated through the ingestion of contaminated food and water. This mechanism of transmission necessitates that an infectious agent survive the low pH and enzyme activity of gastric secretions and the peristaltic action of the intestines in numbers sufficient to establish infection, deemed an infectious dose. Ingested pathogens also must compete successfully with the normal bacterial flora of the bowel for nutritional needs. People with reduced gastric acidity because of disease or medication are more susceptible to infection by this route because the number of ingested microorganisms surviving the gastric environment is greater.

Inhalation

The respiratory tract of healthy people is equipped with a multiple tiered defense system to prevent potential pathogens from entering the lungs. The surface of the respiratory tree
is lined with a layer of mucus that is continuously swept up and away from the lungs and toward the mouth by the beating motion of ciliated epithelial cells. Humidification of inspired air increases the size of aerosolized particles, which are effectively filtered by the mucous membranes of the upper respiratory tract. Coughing also aids in the removal of particulate matter from the lower respiratory tract. Respiratory secretions contain antibodies and enzymes capable of inactivating infectious agents. Particulate matter and microorganisms that ultimately reach the lung are cleared by phagocytic cells.

Despite this impressive array of protective mechanisms, a number of pathogens can invade the human body through the respiratory tract, including agents of bacterial pneumonia (Streptococcus pneumoniae, L. pneumoniae), meningitis (Neisseria meningitidis, Haemophilus influenzae), and tuberculosis, as well as the viruses responsible for measles, mumps, chickenpox, influenza, and the common cold. Defective pulmonary function or mucociliary clearance caused by non-infectious processes such as cystic fibrosis, emphysema, or smoking can increase the risk of inhalation-acquired diseases.

**Source**

The source of an infectious disease refers to the location, host, object, or substance from which the infectious agent was acquired; essentially the “who, what, where, and when” of disease transmission. The source may be endogenous (acquired from the host’s own microbial flora, as would be the case in an opportunistic infection) or exogenous (acquired from sources in the external environment, such as the water, food, soil, or air). The source of the infectious agent can also be another human being, as from mother to child during gestation (congenital infections); an inanimate object; an animal; or a biting arthropod. Inanimate objects that carry an infectious agent are known as fomites. For example, rhinoviruses and many other nonenveloped viruses can be spread by contact with contaminated fomites such as handkerchiefs and toys. Zoonoses are a category of infectious diseases passed from other animal species to humans. Examples of zoonoses include cat-scratch disease, rabies, and visceral or cutaneous larval migrans. The spread of infectious diseases such as Lyme disease through biting arthropod vectors is another route.

**Ms. Roon** acquired Lyme disease through the biting arthropod vector route (spread from other animal species to a human). The organism most likely responsible for her infection is the Borrelia burgdorferi sensu stricto, which is a bacterial spirochete passed to her by the Ixodes scapularis tick (deer tick) that feeds and mates on deer. Since these deer ticks are less than 2 mm, it is easy to miss seeing them attached to one’s body. It takes up to 36 hours of tick attachment for the transfer of borreliae from the infected tick to the person.

Source can denote a place. For instance, infections that develop in people while they are hospitalized are called nosocomial, and those that are acquired outside of health care facilities are called community acquired. The source may also pertain to the body substance that is the most likely vehicle for transmission, such as feces, blood, body fluids, respiratory secretions, and urine. Infections can be transmitted from person to person through shared inanimate objects (fomites) contaminated with infected body fluids. An example of this mechanism of transmission would include the spread of the HIV and hepatitis B virus through the use of shared syringes by intravenous drug users. Infection can also be spread through a complex combination of source, portal of entry, and vector.

**Symptomatology**

The term symptomatology refers to the collection of signs and symptoms expressed by the host during the disease course. This is also known as the clinical picture, or disease presentation, and can be characteristic of any given infectious agent. In terms of pathophysiology, symptoms are the outward expression of the struggle between invading organisms and the retaliatory inflammatory and immune responses of the host. The symptoms of an infectious disease may be specific and reflect the site of infection (e.g., diarrhea, rash, convulsions, hemorrhage, and pneumonia). Conversely, symptoms such as fever, myalgia, headache, and lethargy are relatively nonspecific and can be shared by a number of diverse infectious diseases. The symptoms of a diseased host can be obvious, as in the case of chickenpox or measles. Other, covert symptoms, such as an increased white blood cell count, may require laboratory testing to detect. Accurate recognition and documentation of symptomatology can aid in the diagnosis of an infectious disease.

**Disease Course**

The course of any infectious disease can be divided into several distinguishing stages after the point when the potential pathogen enters the host. These stages are the...
The convalescent period is characterized by the containment of infection, progressive elimination of the pathogen, repair of damaged tissue, and resolution of associated symptoms. Similar to the incubation period, the time required for complete convalescence may be days, weeks, or months, depending on the type of pathogen and the voracity of the host’s immune response. The resolution is the total elimination of a pathogen from the body without residual signs or symptoms of disease.

Several notable exceptions to the classic presentation of an infectious process have been recognized. Chronic infectious diseases have a markedly protracted and sometimes irregular course. The host may experience symptoms of the infectious process continuously or sporadically for months or years without a convalescent phase. In contrast, subclinical or subacute illness progresses from infection to resolution without clinically apparent symptoms. A disease is called insidious if the prodromal phase is protracted; a fulminant illness is characterized by abrupt onset of symptoms with little or no prodrome. Fatal infections are variants of the typical disease course.

**Site of Infection**

Inflammation of an anatomic location is usually designated by adding the suffix -itis to the name of the involved tissue (e.g., bronchitis, infection of the bronchi and bronchioles; encephalitis, brain infection; carditis, infection of the heart). These are general terms, however, and they apply equally to inflammatory processes elsewhere in the human body. Bacteria such as *Helicobacter pylori* are extreme examples of a site-specific pathogen. *Helicobacter pylori* is a significant cause of gastric ulcers but has not been implicated in disease processes elsewhere in the human body. Bacteria such as *N. meningitidis*, a prominent pathogen of children and young adults; *Salmonella typhi*, the cause of typhoid fever; and *B. burgdorferi*, the agent of Lyme disease, tend to disseminate from the primary site of infection to involve other locations and organ systems. These are all examples of systemic pathogens disseminated throughout the body by the circulatory system.
Ms. Roon experienced recurring swelling and aching of two joints over the last 18 months (with no apparent injury). She experiences headaches when her joints are swollen and has felt very tired. In addition, she had a low-grade fever 100 today at the primary care provider’s office. All of these symptoms are examples of the systemic characteristics of Lyme disease. Some of the symptoms may be a result of the inflammatory cascade, which is triggered when she experiences a flare up. Cytokines and complement trigger some tissue injury as they attempt to fight against the Lyme disease. There is no vaccine for Lyme disease so there is no way to absolutely prevent this disease. Ms. Roon had developed antibodies to the disease as evidenced from her positive diagnostic tests. For a positive test, one would need 2 out of 3 of the bands (24 or 21, 39, 41) for an IgM immunoglobulin to be positive for Lyme. And Ms. Roon would need 5 of the following bands (18, 21, or 24, 28, 30, 39, 41, 45, 58, 66, or 93) to have a positive IgG titer for Lyme. Ms. Roon had developed antibodies to the disease as evidenced from her positive diagnostic tests. For a positive test, one would need 2 out of 3 of the bands (24 or 21, 39, 41) for an IgM immunoglobulin to be positive for Lyme. And Ms. Roon would need 5 of the following bands (18, 21, or 24, 28, 30, 39, 41, 45, 58, 66, or 93) to have a positive IgG titer for Lyme.

An abscess is a localized pocket of infection composed of devitalized tissue, microorganisms, and the host’s phagocytic white blood cells. In this case, the dissemination of the pathogen has been contained by the host, but white cell function within the toxic environment of the abscess is hampered, and the elimination of microorganisms is slowed if not actually stopped. Abscesses usually must be surgically drained to obtain a complete cure. Similarly, infections of biomedical implants such as catheters, artificial heart valves, and prosthetic bone implants are seldom cured by the host’s immune response and antimicrobial therapy. The infecting organism colonizes the surface of the implant, producing a dense matrix of cells, host proteins, and capsular material—a biofilm—necessitating the removal of the device.

**Virulence Factors**

Virulence factors are substances or products generated by infectious agents that enhance their ability to cause disease. Although a large number of microbial products fit this description, they can be grouped generally into four categories: toxins, adhesion factors, evasive factors, and invasive factors (Table 12.3).

**Toxins**

Toxins are substances that alter or destroy the normal function of the host or host’s cells. Toxin production is a trait chiefly monopolized by bacterial pathogens, although certain fungal and protozoan pathogens also elaborate substances toxic to humans. Bacterial toxins have a diverse spectrum of activity and exert their effects on a wide variety of host target cells. For classification purposes, however, the bacterial toxins can be divided into two main types: exotoxins and endotoxins.

**Exotoxins.** Exotoxins are proteins released from the bacterial cell during growth. Bacterial exotoxins enzymatically inactivate or modify key cellular constituents, leading to cell death or dysfunction. Diphtheria toxin, for example, inhibits cellular protein synthesis; botulism toxin decreases the release of neurotransmitter from cholinergic neurons, causing flaccid paralysis; tetanus toxin decreases the release of neurotransmitter from inhibitory neurons, producing spastic paralysis; and cholera toxin induces fluid secretion into the lumen of the intestine.

</table>
causing diarrhea. Other examples of exotoxin-induced diseases include pertussis (whooping cough), anthrax, traveler’s diarrhea, toxic shock syndrome, and a host of food-borne illnesses (i.e., food poisoning).

Bacterial exotoxins that produce vomiting and diarrhea are sometimes referred to as enterotoxins. There has been resurgent interest in streptococcal pyrogenic exotoxin A (SPEA), an exotoxin produced by certain strains of group A beta-hemolytic streptococci (S. pyogenes) that causes a life-threatening toxic shock–like syndrome similar to the disease associated with tampon use produced by S. aureus. The streptococcal form of shocklike syndrome is sometimes called Henson disease because it was this infection that caused the death of the famous puppeteer Jim Henson. One study indicated that an intrauterine device grew S. aureus, which caused a fatal case of toxic shock syndrome for a young woman who had been healthy and immunocompetent. Other exotoxins that have gained notoriety include the Shiga toxins produced by Escherichia coli O157:H7 and other select strains. The ingestion of undercooked hamburger meat or unpasteurized fruit juices contaminated with this organism produces hemorrhagic colitis and a sometimes fatal illness called hemolytic uremic syndrome (HUS), characterized by vascular endothelial damage, acute renal failure, and thrombocytopenia. HUS occurs primarily in infants and young children who have not developed antibodies to the Shiga toxins. Over time, the incidence of disease caused by food-borne exotoxins has grown. One such event occurred in the late summer of 2006. Small clusters of infections appeared in sporadic locations throughout the United States. Epidemiologists interviewed affected people and identified fresh spinach as the suspected source of infection. Tracking the outbreaks led investigators from the Centers for Disease Control and Prevention (CDC) to a California produce company bagging fresh spinach.

Endotoxins. In contrast to exotoxins, endotoxins do not contain protein, are not actively released from the bacterium during growth, and have no enzymatic activity. Rather, endotoxins are complex molecules composed of lipid and polysaccharides found in the cell wall of gram-negative bacteria. Studies of different endotoxins have indicated that the lipid portion of the endotoxin confers the toxic properties to the molecule. Endotoxins are potent activators of a number of regulatory systems in humans. A small amount of endotoxin in the circulatory system (endotoxemia) can induce clotting, bleeding, inflammation, hypotension, and fever. The sum of the physiologic reactions to endotoxins is sometimes called endotoxic shock.

Adhesion Factors

No interaction between microorganisms and humans can progress to infection or disease if the pathogen is unable to attach to and colonize the host. The process of microbial attachment may be site specific (e.g., mucous membranes, skin surfaces), cell specific (e.g., T lymphocytes, respiratory epithelium, intestinal epithelium), or nonspecific (e.g., moist areas, charged surfaces). In any of these cases, adhesion requires a positive interaction between the surfaces of host cells and the infectious agent.

The site to which microorganisms adhere is called a receptor, and the reciprocal molecule or substance that binds to the receptor is called a ligand or adhesin. Receptors may be proteins, carbohydrates, lipids, or complex molecules composed of all three. Similarly, ligands may be simple or complex molecules and, in some cases, highly specific structures. Ligands that bind to specific carbohydrates are called lectins. After initial attachment, a number of bacterial agents become embedded in a gelatinous matrix of polysaccharides called a slime or mucous layer. The slime layer serves two purposes: It anchors the agent firmly to host tissue surfaces, and it protects the agent from the immunologic defenses of the host.

Many viral agents, including influenza, mumps, measles, and adenovirus, produce filamentous appendages or spikes called hemagglutinins that recognize carbohydrate receptors on the surfaces of specific cells in the upper respiratory tract of the host.

Evasive Factors

A number of factors produced by microorganisms enhance virulence by evading various components of the host’s immune system. Extracellular polysaccharides, including capsules, slime, and mucous layers, discourage engulfment and killing of pathogens by the host’s phagocytic white blood cells (i.e., neutrophils and macrophages). Encapsulated organisms such as S. agalactiae, S. pneumoniae, N. meningitidis, and H. influenzae type b (before the vaccine) are a cause of significant morbidity and mortality in neonates and children who lack protective anticapsular antibodies. Certain bacterial, fungal, and parasitic pathogens avoid phagocytosis by excreting leukocidin C toxins, which cause specific and lethal damage to the cell membrane of host neutrophils and macrophages. Other pathogens, such as the bacterial agents of salmonellosis, listeriosis, and Legionnaire disease, are adapted to survive and reproduce within phagocytic white blood cells after ingestion, avoiding or neutralizing the usually lethal products contained within the lysosomes of the cell. Helicobacter pylori, the infectious cause of gastritis and gastric ulcers, produces a urease enzyme on its outer cell wall. The urease converts gastric urea into ammonia, thus neutralizing the acidic environment of the stomach and allowing the organism to survive in this hostile environment.

Other unique strategies used by pathogenic microbes to evade immunologic surveillance have evolved solely to avoid recognition by host antibodies. Strains of S. aureus produce a surface protein (protein A) that immobilizes immunoglobulin G (IgG), holding the antigen-binding region harmlessly away from the organisms. This pathogen also secretes a unique enzyme called coagulase. Coagulase converts soluble human coagulation factors into a solid clot, which envelops and protects the organism from phagocytic host cells and antibodies. H. influenzae and N. gonorrhoeae secrete enzymes that cleave and inactivate secretory IgA, neutralizing the primary defense of the respiratory and genital tracts at the site of infection.
**Invasive Factors**

Invasive factors are products produced by infectious agents that facilitate the penetration of anatomic barriers and host tissue. Most invasive factors are enzymes capable of destroying cellular membranes (e.g., phospholipases), connective tissue (e.g., elastases, collagenases), intercellular matrices (e.g., hyaluronidase), and structural protein complexes (e.g., proteases). It is the combined effects of invasive factors, toxins, and antimicrobial and inflammatory substances released by host cells to counter infection that mediate the tissue damage and pathophysiology of infectious diseases.

**Diagnosis**

The diagnosis of an infectious disease requires two criteria: the recovery of a probable pathogen or evidence of its presence from the infected sites of a diseased host, and accurate documentation of clinical signs and symptoms compatible with an infectious process. In the laboratory, the diagnosis of an infectious agent is accomplished using three basic techniques: culture, serology, or the detection of characteristic antigens, genomic sequences, or metabolites produced by the pathogen.

**Culture**

Culture refers to the propagation of a microorganism outside the body, usually on or in artificial growth media such as agar plates or broth. The specimen from the host is inoculated into broth or onto the surface of an agar plate, and the culture is placed in a controlled environment such as an incubator until the growth of microorganisms becomes detectable. In the case of a bacterial pathogen, identification is based on microscopic appearance and Gram stain reaction, shape, texture, and color (i.e., morphology) of the colonies and by a panel of biochemical reactions that fingerprint salient biochemical characteristics of the organism. Certain bacteria such as *Mycobacterium leprae*, the agent of leprosy, and *T. pallidum*, the syphilis spirochete, do not grow on artificial media and require additional methods of identification. Fungi and mycoplasmas are cultured in much the same way as bacteria, but with more reliance on microscopic and colonial morphology for identification.

**Serology**

Serology is an indirect means of identifying infectious agents by measuring serum antibodies in the diseased host. A tentative diagnosis can be made if the antibody level, also called antibody titer, against a specific pathogen rises during the acute phase of the disease and falls during convalescence.
Serologic identification of an infectious agent is not as accurate as culture, but it may be a useful adjunct, especially for the diagnosis of diseases caused by pathogens such as the hepatitis B virus that cannot be cultured. The measurement of antibody titers has another advantage in that specific antibody types, such as IgM and IgG, are produced by the host during different phases of an infectious process. IgM-specific antibodies generally rise and fall during the acute phase of the disease, whereas the synthesis of the IgG class of antibodies increases during the acute phase and remains elevated until or beyond resolution. Older measurements of class-specific antibodies are also useful in the diagnosis of congenital infections. IgM antibodies do not cross the placenta, but certain IgG antibodies are transferred passively from mother to child during the final trimester of gestation. Consequently, an elevated level of pathogen-specific IgM antibodies in the serum of a neonate must have originated from the child and therefore indicates congenital infection. A similarly increased IgG titer in the neonate does not differentiate congenital from maternal infection.

The technology of antigen detection has evolved rapidly over the past decade and in the process has revolutionized the diagnosis of certain infectious diseases. Antigen detection incorporates features of culture and serology but reduces to a fraction the time required for diagnosis. In principle, this method relies on purified antibodies to detect antigens of infectious agents in specimens obtained from the diseased host. The source of antibodies used for antigen detection can be animals immunized against a particular pathogen or hybridomas. Fusing normal antibody-producing spleen cells from an immunized animal with malignant myeloma cells creates hybridomas. The resulting hybrid synthesizes large quantities of antibody. An antibody produced by a hybridoma is called a monoclonal antibody and is highly specific for a single antigen and a single pathogen. Regardless of the source, the antibodies are labeled with a substance that allows microscopic or overt detection when bound to the pathogen or its products. In general, the three types of labels used for this purpose are fluorescent dyes, enzymes, and particles such as latex beads. Fluorescent antibodies allow visualization of an infectious agent with the aid of fluorescence microscopy. Depending on the type of fluorescent dye used, the organism may appear bright green or orange against a black background, making detection extremely easy. Enzyme-labeled antibodies function in a similar manner. The enzyme is capable of converting a colorless compound into a colored substance, thereby permitting detection of antibody bound to an infectious agent without the use of a fluorescent microscope. Particles coated with antibodies clump together, or agglutinate, when the appropriate antigen
FIGURE 12.8 • Polymerase chain reaction. The target DNA is first melted using heat (generally around 94°C) to separate the strands of DNA. Primers that recognize specific sequences in the target DNA are allowed to bind as the reaction cools. Using a unique, thermostable DNA polymerase called Taq and an abundance of deoxynucleoside triphosphates, new DNA strands are amplified from the point of the primer attachment. The process is repeated many times (called cycles) until millions of copies of DNA are produced, all of which have the same length defined by the distance (in base pairs) between the primer binding sites. These copies are then detected by electrophoresis and staining or through the use of labeled DNA probes that, similar to the primers, recognize a specific sequence located in the amplified section of DNA.

is present in a specimen. Particle agglutination is especially useful when examining infected body fluids such as urine, serum, or spinal fluid.

DNA and RNA Sequencing

Methods for identifying infectious agents through the detection of DNA or RNA sequences unique to a single agent have recently seen rapid development and increased use. Several techniques have been devised to accomplish this goal, each having different degrees of sensitivity regarding the number of organisms that need to be present in a specimen for detection. The first of these methods is called DNA probe hybridization. Small fragments of DNA are cut from the genome of a specific pathogen and labeled with compounds (photoemitting chemicals or antigens) that allow detection. The labeled DNA probes are added to specimens from an infected host. If the pathogen is present, the probe attaches to the complementary strand of DNA on the genome of the infectious agent, permitting rapid diagnosis. The use of labeled probes has allowed visualization of particular agents within and around individual cells in histologic sections of tissue.

A second and more sensitive method of DNA detection is called the polymerase chain reaction (PCR; Fig. 12.8). This method incorporates two unique reagents: a specific pair of oligonucleotides (usually less than 25 nucleotides long) called primers and a heat-stable DNA polymerase. To perform the assay, the primers are added to the specimen containing the suspect pathogen, and the sample is heated to melt the DNA in the specimen and then allowed to cool. The primers locate and bind only to the complementary target DNA of the pathogen in question. The heat-stable polymerase begins to replicate the DNA from the point at which the primers attached, similar to two trains approaching one another on separate but converging tracks. After the initial cycle, DNA polymerization ceases at the point where the primers were located, producing a strand of DNA with a distinct size, depending on the distance separating the two primers. The specimen is heated again, and the process starts anew. After many cycles of heating, cooling, and polymerization, a large number of uniformly sized DNA fragments are produced only if the specific pathogen (or its DNA) is present in the specimen. The polymerized DNA fragments are separated by electrophoresis and visualized with a dye or identified by hybridization with a specific probe.

A modification of PCR, known as real-time PCR, continues to revolutionize medical diagnostics. Real-time PCR uses the same principles as PCR, but includes a fluorescence-labeled probe that specifically binds a target DNA sequence between the oligonucleotide primers. As the DNA is replicated by the DNA polymerase, the level of fluorescence in the reaction is measured. If fluorescence increases beyond a minimum threshold, the PCR is considered positive and indicates the presence of the target DNA in a specimen. Real-time PCR is very effective in determining the diagnosis of Clostridium difficile. It is quicker, more sensitive, and more specific and can assist the physician/provider in administering antibiotics more efficiently for people with diarrhea secondary to C. difficile.

Several variations of molecular gene detection techniques in addition to PCR have been developed and incorporated into diagnostic kits for use in the clinical laboratory, including ligase chain reaction (LCR), transcription-mediated amplification (TMA), strand displacement amplification, branched-chain DNA signal amplification (bDNA), hybrid capture assays, and DNA sequencing.

Many of the gene detection technologies have been adapted for quantitation of the target DNA or RNA in serum specimens of patients infected with viruses such as HIV and
hepatitis C. If the therapy is effective, viral replication is suppressed and the viral load (level of viral genome) in the peripheral blood is reduced. Conversely, if mutations in the viral genome lead to resistant strains or if the antiviral therapy is ineffective, viral replication continues and the person’s viral load rises, indicating a need to change the therapeutic approach.

Molecular biology has revolutionized medical diagnostics. Using techniques such as PCR, laboratories now can detect as little as one virus or bacterium in a single specimen, allowing for the diagnosis of infections caused by microorganisms that are impossible or difficult to grow in culture. These methods have increased sensitivity while decreasing the time required to identify the etiologic agent of infectious disease. For example, using standard viral culture, it can take days to weeks to grow a virus and correlate the CPE with the virus. Using molecular biologic techniques, laboratories are able to complete the same work in a few hours.

KEY POINTS

**DIAGNOSIS AND TREATMENT OF INFECTIOUS DISEASES**

- The definitive diagnosis of an infectious disease requires recovery and identification of the infecting organism by microscopic identification of the agent in stains of specimens or sections of tissue, culture isolation and identification of the agents, demonstration of antibody- or cell-mediated immune responses to an infectious agent, or DNA or RNA identification of infectious agents.
- Treatment of infectious disease is aimed at eliminating the infectious organism and promoting recovery of the infected person. Treatment is provided through the use of antimicrobial agents, immunotherapy, and, when necessary, surgical intervention. Prevention of infectious disease is accomplished through the use of immunization methods.

**Treatment**

The goal of treatment for an infectious disease is complete removal of the pathogen from the host and the restoration of normal physiologic function to damaged tissues. Most infectious diseases of humans are self-limiting in that they require little or no medical therapy for a complete cure. When an infectious process gains the upper hand and therapeutic intervention is essential, the choice of treatment may be medicinal through the use of antimicrobial agents; immunologic with antibody preparations, vaccines, or substances that stimulate and improve the host’s immune function; or surgical by removing infected tissues. The decision about which therapeutic modality or combination of therapies to use is based on the extent, urgency, and location of the disease process, the pathogen, and the availability of effective antimicrobial agents.

**Antimicrobial Agents**

Antimicrobial agents are generally called **antibiotics**. Most antibiotics are actually produced by other microorganisms, primarily bacteria and fungi, as by-products of metabolism. Antibiotics usually are effective only against other prokaryotic organisms. An antibiotic is considered **bactericidal** if it causes irreversible and lethal damage to the bacterial pathogen and **bacteriostatic** if its inhibitory effects on bacterial growth are reversed when the agent is eliminated. Antibiotics can be classified into families of compounds with related chemical structure and activity (Table 12.4).

Not all antibiotics are effective against all pathogenic bacteria. Some agents are effective only against gram-negative bacteria, and others are specific for gram-positive organisms (e.g., vancomycin). The so-called broad-spectrum antibiotics, such as the newest class of cephalosporins, are active against a wide variety of gram-positive and gram-negative bacteria. Members of the **Mycobacterium** genus, including *M. tuberculosis*, are extremely resistant to the effects of the major classes of antibiotics and require an entirely different spectrum of agents for therapy. The four basic mechanisms of the antibiotic action are interference with a specific step in bacterial cell wall synthesis (e.g., penicillins, cephalosporins, glycopeptides, monobactams, carbapenems), inhibition of bacterial protein synthesis (e.g., aminoglycosides, macrolides, ketolides, tetracyclines, chloramphenicol, oxazolidinones, streptogramins, and rifampin), interruption of nucleic acid synthesis (e.g., fluoroquinolones, nalidixic acid), and interference with normal metabolism (e.g., sulfonamides, trimethoprim).22

Despite lack of antibiotic activity against eukaryotic cells, many agents cause unwanted or toxic side effects in humans, including allergic responses (penicillins, cephalosporins, sulfonamides, glycopeptides), hearing and kidney impairment (aminoglycosides), and liver or bone marrow toxicity (chloramphenicol, fluoroquinolones, vancomycin). Of greater concern is the increasing prevalence of bacteria resistant to the effects of antibiotics. The ways in which
bacteria acquire resistance to antibiotics are becoming as numerous as the types of antibiotics. Bacterial resistance mechanisms include the production of enzymes that inactivate antibiotics, such as $\beta$-lactamases; genetic mutations that alter antibiotic binding sites; alternative metabolic pathways that bypass antibiotic activity; and changes in the filtration qualities of the bacterial cell wall that prevent access of antibiotics to the target site in the organism. It is the continuous search for a “better mousetrap” that makes anti-infective therapy such a fascinating aspect of infectious diseases.

**Antiviral Agents.** Until recently, few effective antiviral agents were available for treating human infections. The reason for this is host toxicity. Viral replication requires the use of eukaryotic host cell enzymes, and the drugs that effectively interrupt viral replication are likely to interfere with host cell reproduction as well. However, in response to the AIDS epidemic, there has been massive, albeit delayed, development of antiretroviral agents. Almost all antiviral compounds are synthetic and, with few exceptions, the primary target of antiviral compounds is viral RNA or DNA synthesis. Agents such as acyclovir, ganciclovir, vidarabine, and ribavirin mimic the nucleoside building blocks of RNA and DNA. During active viral replication, the nucleoside analogs inhibit the viral DNA polymerase, preventing duplication of the viral genome and spread of infectious viral progeny to other susceptible host cells. Similar to the specificity of antibiotics, antiviral agents may be active against RNA viruses only, DNA viruses only, or occasionally both. Other nucleoside analogs, such as zidovudine, lamivudine, didanosine, stavudine, and zalcitabine, and nonnucleoside inhibitors, including nevirapine, efavirenz, and delavirdine, were developed specifically for the treatment of AIDS by targeting the HIV-specific enzyme, reverse transcriptase, for inhibition. This key enzyme is essential for viral replication and has no counterpart in the infected eukaryotic host cells.

Another class of antiviral agents developed solely for the treatment of HIV infections are the protease inhibitors (e.g., indinavir, ritonavir, saquinavir, tipranavir, atazanavir, nelfinavir). These drugs inhibit an HIV-specific enzyme that is necessary for late maturation events in the virus life cycle.

The table above lists various classes of antibiotics, their example, target site, and side effects. Each class of antibiotics is associated with specific target sites in the bacterial cell and various side effects that can be observed in patients.
Experimental approaches to antiviral therapy include compounds that inhibit viral attachment to susceptible host cells, drugs that prevent uncoating of the viral genome once inside the host cell, and agents that directly inhibit viral DNA polymerase. A class of antiviral agents that specifically inhibits influenza virus neuraminidase B, which is an essential enzyme for viral replication, has also been effective with influenza. Two agents in this class, zanamivir and oseltamivir, are used for treatment of both influenza A and B.

Although the treatment of viral infections with antimicrobial agents is a relatively recent endeavor, reports of viral mutations resulting in resistant strains are very common. This is especially troubling in the case of HIV, in which resistance to relatively new antiviral agents, including nucleoside analogs and protease inhibitors, has already been described, prompting the need for combination or alternating therapy with multiple antiretroviral agents.

Antifungal Agents. The target site of the two most important families of antifungal agents is the cytoplasmic membranes of yeasts or molds. Fungal membranes differ from human cell membranes in that they contain the sterol ergosterol instead of cholesterol. The polyene family of antifungal compounds (e.g., amphotericin B, nystatin) preferentially binds to ergosterol and forms holes in the cytoplasmic membrane, causing leakage of the fungal cell contents and, eventually, lysis of the cell.22 The imidazole class of drugs (e.g., fluconazole, itraconazole, voriconazole, posaconazole) inhibits the synthesis of ergosterol, thereby damaging the integrity of the fungal cytoplasmic membrane.22 Both types of drugs bind to a certain extent to the cholesterol component of host cell membranes and elicit a variety of toxic side effects in treated patients. The nucleoside analog 5-fluorocytosine (5-FC) disrupts fungal RNA and DNA synthesis but without the toxicity associated with the polyene and imidazole drugs. Unfortunately, 5-FC demonstrates little or no antifungal activity against molds or dimorphic fungi and is primarily reserved for infections caused by yeasts.

A novel class of antifungal compounds called echinocandins has received considerable attention because these drugs inhibit the synthesis of β-1,3-glucan, a major cell wall polysaccharide found in many fungi, including *C. albicans*, *Aspergillus* species, and *Pneumocystis carinii*.22 The drugs included in this class are caspofungin, micafungin, and anidulafungin. These inhibitors are available for treatment of people with fungal infections, such as candidiasis or invasive aspergillosis, which are refractory to treatment with other antifungal agents.

Antiparasitic Agents. Because of the extreme diversity of human parasites and their growth cycles, a review of antiparasitic therapies and agents would be highly impractical and lengthy. Similar to other infectious diseases caused by eukaryotic microorganisms, treatment of parasitic illnesses is based on exploiting essential components of the parasite’s metabolism or cellular anatomy that are not shared by the host. Any relatedness between the target site of the parasite and the cells of the host increases the likelihood of toxic reactions in the host.

Resistance among human parasites to standard, effective therapy is a major concern. In Africa, Asia, and South America, the incidence of chloroquine-resistant malaria (*Plasmodium falciparum*) is on the rise. Resistant strains require more complicated, expensive, and potentially toxic therapy with a combination of agents.

**Immunotherapy**

An exciting approach to the treatment of infectious diseases is immunotherapy. This strategy involves supplementing or stimulating the host’s immune response so that the spread of a pathogen is limited or reversed. Several products are available for this purpose, including intravenous immunoglobulin (IVIG) and cytokines. IVIG is a pooled preparation of antibodies obtained from normal, healthy immune human donors that is infused as an intravenous solution. In theory, pathogen-specific antibodies present in the infusion facilitate neutralization, phagocytosis, and clearance of infectious agents above and beyond the capabilities of the diseased host. Hyperimmune immunoglobulin preparations, which are also commercially available, contain high titers of antibodies against specific pathogens, including hepatitis B virus, cytomegalovirus, rabies, and varicella–zoster virus.

Cytokines are substances produced by various cells that, in small quantities, stimulate white cell replication, phagocytosis, antibody production, and the induction of fever, inflammation, and tissue repair—all of which counteract infectious agents and hasten recovery. With the advent of genetic engineering and cloning, many cytokines, including interferons and interleukins, have been produced in the laboratory and are being evaluated experimentally as anti-infective agents. As we learn more about the action of cytokines, it becomes evident that some of the adverse reactions associated with infectious processes result from the body’s own inflammatory response. Interventional therapies designed to inactivate certain cytokines such as tumor necrosis factor have proven to be helpful in animal models of infection. It is not unlikely that therapies based on the regulation of the inflammatory response will become widely used over the next few years.

One of the most efficient but often overlooked means of preventing infectious diseases is immunization. Proper and timely adherence to recommended vaccination schedules in children and booster immunizations in adults effectively reduces the senseless spread of vaccine-preventable illnesses such as measles, mumps, pertussis, and rubella, which still occur with alarming frequency. New strategies for the development of vaccines carried by harmless viral vectors are currently being developed that someday might lead to inexpensive and effective oral immunization against HIV, hepatitis C, malaria, and other potentially lethal infectious diseases.

**Surgical Intervention**

Before the discovery of antimicrobial agents, surgical removal of infected tissues, organs, or limbs was occasionally the only
option available to prevent the demise of the infected host. Today, medicinal therapy with antibiotics and other anti-infective agents is an effective solution for most infectious diseases. However, surgical intervention is still an important option for cases in which the pathogen is resistant to available treatments. Surgical interventions may be used to hasten the recovery process by providing access to an infected site by antimicrobial agents (drainage of an abscess), cleaning the site (debridement), or removing infected organs or tissue (e.g., appendectomy). In some situations, surgery may be the only means of affecting a complete cure, as in the case of endocarditis resulting in an infected heart valve, in which the diseased valve must be replaced with a mechanical or biologic valve to restore normal function. In other situations, surgical containment of a rapidly progressing infectious process such as gas gangrene may be the only means of saving a person’s life.

IN SUMMARY

The ultimate outcome of any interaction between microorganisms and the human host is decided by a complex and ever-changing set of variables that take into account the overall health and physiologic function of the host and the virulence and infectious dose of the microbe. In many instances, disease is an inevitable consequence, but with continuing advances in science and technology, the majority of cases can now be eliminated or rapidly cured with appropriate therapy. It is the intent of those who study infectious diseases to understand thoroughly the pathogen, the disease course, the mechanisms of transmission, and the host response to infection. This knowledge will lead to development of improved diagnostic techniques, revolutionary approaches to anti-infective therapy, and eradication or control of microscopic agents that cause frightening devastation and loss of life throughout the world.

BIOTERRORISM AND EMERGING GLOBAL INFECTIOUS DISEASES

After completing this section of the chapter, you should be able to meet the following objectives:

- List the infectious agents considered to pose the highest level of bioterrorism threat.
- State an important concept in containment of infections due to bioterrorism and global travel.

Bioterrorism

In October of 2001, less than 1 month after the tragedy of September 11, the world became instantly acquainted with the term bioterrorism. By the end of November of that year, 22 cases of human anthrax (11 cutaneous and 11 inhalation) had been identified, resulting in five deaths, and all cases were associated with exposure to four intentionally contaminated envelopes delivered through the U.S. Postal Service. The reality of the 2001 outbreak brought a new sense of awareness concerning the use of microorganisms as weapons.23,24

Anthrax is an ancient disease caused by the cutaneous inoculation, inhalation, or ingestion of the spores of Bacillus anthracis, a gram-positive bacillus. Anthrax is more commonly known as a disease of herbivores that can be transmitted to humans through contact with infected secretions, soil, or animal products. It is a rare disease in the United States, and so the sudden increase in cases over a short time was a chilling indication that the spread of the organism had been intentional. Fortunately, the number of deaths was limited thanks to prompt recognition of cases by physicians and public health personnel and rapid institution of antimicrobial prophylaxis to exposed people.

To prepare for the possibility of bioterrorist attacks, the CDC along with other federal, state, and local agencies has created the laboratory response network (LRN). The LRN is a four-tiered structure consisting of laboratories with ever-increasing expertise, responsibility, and biocontainment facilities that allow for the rapid and coordinated detection and identification of bioterrorism events under safe working conditions.25

Potential agents of bioterrorism have been categorized into three levels (A, B, C) based on risk of use, transmissibility, invasiveness, and mortality rate. The agents placed in the highest bioterrorism threat level include Bacillus anthracis, Yersinia pestis (the cause of bubonic plague), Francisella tularensis (the cause of tularemia), variola major virus (the cause of smallpox), and several hemorrhagic fever viruses (Ebola, Marburg, Lassa, and Junin). The toxin of the anaerobic gram-positive organism Clostridium botulinum, which causes the neuromuscular paralysis termed botulism, is also listed as a category A agent. Interestingly, purified Clostridium botulinum toxins A and B are finding increasing use under the trade names Botox, Myobloc, and NeuroBloc for various medicinal and cosmetic purposes. The category B agents include agents of food-borne and water-borne diseases (Salmonella, Shigella, Vibrio cholerae, E. coli O157:H7), zoonotic infections (Brucella species, C. burnetii, Burkholderia mallei), and viral encephalitides (Venezuelan, Western, and Eastern equine encephalitis viruses), as well as toxins from Staphylococcus aureus, Clostridium perfringens, and Ricin communis (the castor bean). Category C agents are defined as emerging pathogens and potential risks for the future, even though many of these organisms are causes of ancient diseases. Category C agents include Mycobacterium tuberculosis, Nipah virus, hantavirus, tick-borne and yellow fever viruses, and the only protozoan of the group, Trypanosoma cruzi (Chagas disease). An excellent Web site available through the CDC is the “CDC Public Health Emergency Preparedness & Response Site,” which provides detailed information on agents of bioterrorism, emergency contacts, and contingency plans in the event of an outbreak (www.bt.cdc.gov).26
Global Infectious Diseases

Aided by a global market and the ease of international travel, the first years of the 21st century have witnessed the importation or emergence of a host of novel infectious diseases. During the late summer and early fall of 1999, West Nile virus (WNV an arthropod-borne flavivirus) was identified as the cause of an epidemic involving 56 people in the New York City area. This outbreak, which led to seven deaths (primarily in older adults), marked the first time that WNV had been recognized in the Western Hemisphere since its discovery in Uganda nearly 60 years earlier. Because WNV is a mosquito-borne disease and is transmitted to a number of susceptible avian (e.g., blue jays, crows, and hawks) and equine hosts, the potential for rapid and sustained spread of the disease across the United States was appreciated early. By the fall of 2002, a national surveillance network had detected WNV activity in 2289 counties from 44 states, including Los Angeles County, and had identified more than 3000 human cases. The disease ranges in intensity from a nonspecific febrile illness to fulminant meningoencephalitis. In 2002 alone, 3389 cases of WNV-associated illness were identified in the United States with 201 deaths, making this the largest arboviral meningoencephalitis outbreak ever described in the Western Hemisphere. Efforts to prevent further spread of the disease are currently centered on surveillance of WNV-associated illness in birds, humans, and other mammals, as well as mosquito control. In the winter of 2002, SARS emerged as a global threat. The first inkling of the impending threat was when the Chinese Ministry of Health reported 305 cases of a mysterious and virulent respiratory tract illness that had appeared in Guangdong province in southern China in a 4-month period of time. The spread of the disease to household contacts of sick people and medical personnel caring for people with the disease identified it as highly transmissible. In a very short time, people with compatible symptoms were recognized in Hong Kong and Vietnam. The World Health Organization (WHO) promptly issued a global alert and started international surveillance for patients with typical symptomatology who had a history of travel to the endemic region. As of June 2003, more than 8000 cases of SARS from 29 countries and 809 deaths were reported to the WHO. In a remarkable feat of molecular technology, the etiology of SARS was quickly determined to be a novel coronavirus, possibly of mammalian or avian origin, and its entire genome was sequenced by the end of May 2003. In May of 2003, a child was seen in central Wisconsin for fever, lymphadenopathy, and a papular rash. Electron microscopic examination of tissue from one of the child’s skin lesions revealed a virus that morphologically resembled poxvirus, obviously generating some concern because of the awareness of the potential for bioterrorism using smallpox virus. However, the same virus was identified from a lymph node biopsy of the child’s ill pet prairie dog. Additional testing of the child and the prairie dog specimens indicated that the virus was a monkeypox virus, one of the orthopoxvirus family of viruses. By the beginning of June, 53 possible cases of monkeypox infection were being followed in Wisconsin, Illinois, and Indiana. Epidemiologic investigations conducted by state and federal health care agencies identified the potential source of the virus as nine different species of small mammals, including Gambian giant rats that had been imported from Ghana in April and were housed in common facilities with prairie dogs. A number of these animals were then shipped to a pet distributor in Illinois and subsequently sold to the public. These three scenarios highlight the rapidity with which novel or exotic diseases can be introduced into nonindigenous regions of the world and to a susceptible population. Although great strides in molecular microbiology have allowed for the rapid identification of new or rare microorganisms, the potential devastation in terms of human life and economic loss is great, underscoring the need to maintain resources for public health surveillance and intervention. For more details on these and other intriguing cases of infectious disease detective work, refer to these excellent Web sites: www.who.int/en/ and www.cdc.gov.

IN SUMMARY

The challenges associated with maintaining health throughout a global community are becoming increasingly apparent. Aided by a global market and the ease of international travel, the past decade has witnessed the importation and emergence of a host of novel infectious diseases. There is also the potential threat of the deliberate use of microorganisms as weapons of bioterrorism.

REVIEW EXERCISES

1. Newborn infants who have not yet developed an intestinal flora are routinely given an intramuscular injection of vitamin K to prevent bleeding due to deficiency in vitamin K–dependent coagulation factors. 
   A. Use the concept of mutualism to explain why this is done.
2. People with human granulocytic ehrlichiosis may be coinfected with Lyme disease.
   A. Explain.
3. People with chronic lung disease are often taught to contact their health care provider when they notice a change in the color of their sputum (i.e., from white or clear to yellow- or brown-tinged) because it might be a sign of a bacterial infection.
   A. Explain.
4. Microorganisms are capable of causing infection only if they can grow at the temperature of the infected body site.
A. Using this concept, explain the different sites of fungal infections due to the dermatophyte fungal species that cause tinea pedis (athlete’s foot), and Candida albicans, which causes infections of the mouth (thrush) and female genitalia (vulvovaginitis).

5. The threat of global infections, such as SARS and HIV, continues to grow.
A. What would you propose to be one of the most important functions of health care professionals in terms of controlling the spread of such infections?

The human body is constantly exposed to potentially deleterious microorganisms and foreign substances. Therefore, it has evolved a complete system composed of complementary and interrelated mechanisms to defend against invasion by bacteria, viruses, and other foreign substances. Through recognition of molecular patterns, the body’s immune system can distinguish itself from these foreign substances and can discriminate potentially harmful from nonharmful agents. In addition, it can defend against abnormal cells and molecules that periodically develop. The skin and its epithelial layers in conjunction with the body’s normal inflammatory processes make up the first line of the body’s defense and confer innate or natural immunity to the host. Once these protective barriers have been crossed, the body relies upon a second line of defense known as the adaptive immune response to eradicate infection by invading organisms. The adaptive immune response develops slowly over time but results in the development of antibodies capable of targeting specific microorganisms and foreign substances should a second exposure occur.

This chapter covers immunity and the immune system, including a complete discussion of innate and adaptive immunity. Concepts related to key cellular function, recognition systems, and effector responses integral to the immune system are also presented. In addition, developmental aspects of the immune system are discussed.
Cytokines and Their Role in Immunity

The ability of the cells of both the innate and adaptive immune systems to communicate critical information with each other by cell-to-cell contact and initiate end effector responses is dependent upon the secretion of short-acting, biologically active, soluble molecules called cytokines. Cytokines are an essential component of host defense mechanisms and the primary means with which cells of innate and adaptive immunity interact. Chemokines are a subset of cytokines that consist of small protein molecules involved in both immune and inflammatory responses. They are responsible for directing leukocyte migration to areas of injury and to locations where primary immune responses are initiated such as lymph nodes, the spleen, Peyer patches, and the tonsils. The source and function of the main cytokines that participate in innate and adaptive immunity are summarized in Table 13.2.

General Properties of Cytokines

Cytokines are low molecular weight, regulatory, pro- or anti-inflammatory proteins that are produced by cells of the innate and adaptive immune systems and that mediate many of the actions of these cells. The majority of the functionally important cytokines are interleukins (ILs), interferons (IFNs), and tumor necrosis factor alpha (TNF-α). Cytokines generate their responses by binding to specific receptors on their target cells and activating G-protein–coupled receptors.

Interleukins (ILs) are produced by macrophages and lymphocytes in response to the presence of an invading microorganism or activation of the inflammatory process. Their primary function is to enhance the acquired immune response through alteration of molecular expression, induction of leukocyte maturation, enhanced leukocyte chemotaxis, and general suppression or enhancement of the inflammatory process.

</table>

CSF, colony-stimulating factor; NK, natural killer; T, H, T-helper type 1; T, H, T-helper type 2; MHC, major histocompatibility complex.

IFNs are cytokines that primarily protect the host against viral infections and play a role in the modulation of the inflammatory response. IFNs are cell-type specific with IFN-α and IFN-β produced primarily by macrophages and IFN-γ produced primarily by T lymphocytes. TNF-α, a cytokine in a class by itself, is one of the most important mediators of the inflammatory response and is produced by macrophages when surface toll-like receptors (TLRs) recognize pathogen-associated molecular patterns (PAMPs) on the surface of microorganisms. TNF-α acts as an endogenous pyrogen (fever producer) and induces synthesis of proinflammatory substances in the liver. With prolonged exposure, it has the ability to cause intravascular coagulation and subsequent thrombosis production.

Despite the diverse functions of the cytokines, they all share certain important properties. All cytokines are secreted in a brief, self-limited manner. They are rarely stored as pre-
formed molecules but rather are synthesized through transcription as a result of cellular activation. The actions of cytokines are often pleiotropic, meaning that they have the ability to allow a single cytokine to act on different cell types. For example, IL-17 is produced by the T-helper 17 (T\(_7\),H) cells and acts on several cell types including leukocytes, epithelial cells, mesothelial cells, vascular endothelial cells, and fibroblasts. As a result, T\(_7\),H cells play a critical role in host defense against pathogens that infiltrate the mucosal barrier. Although pleiotropism allows cytokines to mediate diverse effects, it greatly limits their use for therapeutic purposes because of numerous unwanted side effects. Redundancy refers to the ability of different cytokines to stimulate the same or overlapping biologic functions. Because of this redundancy, antagonists against a single cytokine may not have functional consequences because other cytokines may compensate.

In addition to being pleiotropic and redundant, cytokines can have broad activity. Therefore, several different cell types are capable of producing a single cytokine. For example, IL-1 is a proinflammatory cytokine that is primarily produced by macrophages but can be produced by virtually all leukocytes, endothelial cells, and fibroblasts. Cytokines also function to initiate cascade functions with one cytokine influencing the synthesis and actions of other cytokines. Often the second and third cytokines may mediate the biologic effects of the first cytokine. These effects may be localized, acting on a single cell or group of cells in the area surrounding the effector cell, or the effects can be systemic with the cytokines secreted into the bloodstream and transported to their site of action. TNF-\(\alpha\) is an example of a cytokine with wide-reaching systemic effects. Cytokines may also serve as antagonists to inhibit the action of another cytokine and as a result act as anti-inflammatory cytokines. IL-110 is an anti-inflammatory cytokine to down-regulate the inflammatory and adaptive immune responses.

**Chemokines**

Chemokines are small protein molecules (70 to 130 amino acids) that are involved in immune and inflammatory cellular responses and function to control the migration of leukocytes to their primary site of action in the immune response. There are four distinct classes of chemokines (C, CC, CXC, and CX3C), which are named for the number and location of cysteine residues on the terminal amino acid of the protein. Currently, 48 distinct chemokine molecules have been identified within the four different classes. The vast majority of these are classified as either CC or CXC chemokines. The CC chemokines have the first two cysteine molecules adjacent to each other, while these molecules are separated by an amino acid in the CXC chemokines. The CC chemokines attract monocytes, lymphocytes, and eosinophils to sites of chronic inflammation. The CXC chemokines attract neutrophils to sites of acute inflammation.

Chemokines are named according to structure, followed by “L” and the number of their gene (e.g., CCL1, CXCL1). Likewise, chemokine receptors are named according to the structure, followed by an “R” and a number (e.g., CCR1, CXCR1). Six receptors for CXC (CXCRs) and 10 for CC (CCRs) chemokines have been characterized in terms of their structure and function. Chemokines communicate with their target cells by activating G-protein-coupled receptors that are pertussis toxin sensitive and as a result are capable of activating different populations of leukocytes, thereby controlling the migration of immune cells to their sites of action based upon the needs of the situation. Most receptors recognize more than one chemokine, and most chemokines recognize more than one receptor. Binding of a chemokine to a receptor can result in inhibition or activation with the same chemokine acting as an activator at one type of receptor and as an inhibitor at another. Chemokines are implicated in a number of acute and chronic diseases, including atherosclerosis, rheumatoid arthritis, inflammatory bowel disease (Crohn disease, ulcerative colitis), allergic asthma and chronic bronchitis, multiple sclerosis, systemic lupus erythematosus, and HIV infection. They also play a role in the body’s immune response against cancer cells through the up-regulation of CCL21 and other chemokines by activated T cells and other tumor-derived proteins.

**Colony-Stimulating Factors**

Colony-stimulating factors (CSFs) encompass a subset of cytokines that participate in hematopoiesis by stimulating bone marrow pluripotent stem and progenitor or precursor cells to produce large numbers of mature platelets, erythrocytes, lymphocytes, neutrophils, monocytes, eosinophils, basophils, and dendritic cells (DCs). The CSFs were named according to the type of target cell on which they act (see Table 13.2). Macrophages, endothelial cells, and fibroblasts produce granulocyte colony-stimulating factor (G-CSF) during times of stress and inflammation where it promotes growth and maturation of neutrophils. Granulocyte/monocyte colony-stimulating factor (GM-CSF) acts on the granulocyte-monocyte progenitor cells to produce monocytes, neutrophils, and DCs, and monocyte colony-stimulating factor (M-CSF) stimulates the mononuclear phagocyte progenitor. While CSF is necessary for normal blood cell production and maturation, excess CSF production has been implicated in several disease processes and the development of corticosteroid-resistant chronic obstructive pulmonary disease (COPD). Impaired macrophage function and subsequent impairment of G-CSF activity have been associated with the development of neutrophilia in animal studies. In clinical practice, recombinant CSF is being used to increase the success rates of bone marrow transplantations. The availability of recombinant CSFs and cytokines offers the possibility of several clinical therapies where stimulation or inhibition of the immune response or cell production is desirable.
Innate immunity (also called natural immunity) consists of the cellular and biochemical defenses that are in place before an encounter with an infectious agent and provide rapid protection against infection. The major effector components of innate immunity include epithelial cells, which block the entry of infectious agents and secrete antimicrobial enzymes, proteins, and peptides; phagocytic neutrophils and macrophages, which engulf and digest microbes; natural killer (NK) cells, which kill intracellular microbes and foreign agents; and the complement system, which amplifies the inflammatory response and uses the membrane attack response to lyse microbes. The cells of the innate immune system also produce chemical messengers that stimulate and influence the adaptive immune response.

The innate immune system uses pattern recognition receptors that recognize microbial structures (e.g., sugars, lipid molecules, proteins) that are shared by microbes and are often necessary for their survival, but are not present on human cells. Thus, the innate immune system is able to distinguish between self and nonself, but is unable to distinguish between agents.
Adaptive Immunity

Adaptive immunity (also called *acquired immunity*) refers to immunity that is acquired through previous exposure to infectious and other foreign agents. A defining characteristic of adaptive immunity is the ability not only to distinguish self from nonself but to recognize and destroy specific foreign agents based on their distinct antigenic properties. The components of the adaptive immune system are the T and B lymphocytes and their products. There are two types of adaptive immune responses, humoral and cell-mediated immunity, that function to eliminate different types of microbes.

Humoral immunity is mediated by the B lymphocytes (B cells) and is the principal defense against extracellular microbes and their toxins. The B cells differentiate into antibody-secreting plasma cells. The circulating antibodies then interact with and destroy the microbes that are present in the blood or mucosal surfaces.

Cell-mediated, or cellular, immunity is mediated by the cytotoxic T lymphocytes (T cells) and functions in the elimination of intracellular pathogens (e.g., viruses). T cells develop receptors that recognize the viral peptides displayed on the surface of infected cells and then signal destruction of the infected cells.

IN SUMMARY

Immunity is the body’s defense against disease and invading microorganisms. Immune mechanisms can be divided into two types: innate and adaptive immunity. Innate immunity is the first line of defense and can distinguish between self and nonself through the recognition of cellular patterns on foreign substances and microbes. Adaptive immunity is part of the second line of defense and involves both humoral and cellular mechanisms that respond to cell-specific substances known as antigens. The adaptive immune response is capable of amplifying and sustaining its responses, of distinguishing self from nonself, and finally of memory in that it can recognize the antigen on repeat exposure in order to quickly produce a heightened response on subsequent encounters with the same microorganism. The innate and adaptive immune responses work in concert with one another to ensure that the homeostasis is maintained.

Although cells of both the innate and adaptive immune systems communicate critical information about the invading microbe or pathogen by cell-to-cell contact, many interactions and cellular responses depend on the secretion of chemical mediators in the form of cytokines, chemokines, and CSFs. Cytokines are soluble proteins secreted by cells of both the innate and adaptive immune systems that mediate many of the functions of these cells. Chemokines are cytokines that stimulate the migration and activation of various immune and inflammatory cells. CSFs stimulate the growth and differentiation of bone marrow progenitors of immune cells and play a key role in hematopoiesis.
The innate immune system is comprised of two separate but interrelated lines of defense: the epithelial layer, which acts as a physical barrier to invading substances and organisms, and the inflammatory response. The innate immune response utilizes the body’s natural epithelial barriers along with phagocytic cells (mainly neutrophils and macrophages), natural killer (NK) cells, and several plasma proteins, including kinins, clotting factors, and those of the complement system, to maintain internal homeostasis. The innate immune response relies on the body’s ability to distinguish evolutionarily conserved structures on pathogens known as PAMPs from structures on human cells. The response of the innate immune system is rapid, usually within minutes to hours, and prevents the establishment of infection and deeper tissue penetration of microorganisms. The innate immune response is usually very effective against most pathogens. However, when the innate response is overwhelmed, adaptive immune responses become activated as the final line of defense against invading organisms. Innate immune mechanisms are always present in the body before an encounter with an infectious agent and are rapidly activated by microorganisms and foreign substances. Therefore, the body’s defenses are in full swing before the development of the adaptive immune response. The innate immune system also interacts with and directs adaptive immune responses.

Under normal conditions, the innate immune response is essential to the continued health and well-being of the body. However, during times of hyperresponsiveness or hyporesponsiveness, the innate immune system plays a role in the pathogenesis of disease. One of the main functions of the innate immune system is the initiation of the inflammatory response, which involves the activation of a complex cascade of events and chemical mediators. As part of the innate immune response, inflammation plays a key role in the pathogenesis of many common pathophysiologic states including atherosclerosis and coronary artery disease, bronchial asthma, non-insulin-dependent diabetes mellitus (NIDDM), rheumatoid arthritis, multiple sclerosis, and systemic lupus erythematosus.

Epithelial Barriers

Physical, mechanical, and biochemical barriers against microbial invasion are found in all common portals of entry into the body, including the skin and respiratory, gastrointestinal, and urogenital tracts. The intact skin is by far the most formidable physical barrier available to infection because of its design. It is comprised of closely packed cells that are organized in multiple layers that are continuously shed. In addition, a protective layer of protein, known as keratin, covers the skin. The skin has simple chemicals that create a nonspecific, salty, acidic environment and antibacterial proteins, such as the enzyme lysozyme, that inhibit the colonization of microorganisms and aid in their destruction. The complexity of the skin becomes evident in cases of contact dermatitis where increased susceptibility to cutaneous infection occurs as the result of abnormalities of the innate immune response including defects in the epithelial layer itself and defects in both signaling and expression of innate responses.

Sheets of tightly packed epithelial cells line and protect the gastrointestinal, respiratory, and urogenital tracts and physically prevent microorganisms from entering the body. These cells destroy the invading organisms by secreting antimicrobial enzymes, proteins, and peptides. Specialized cells in these linings, such as the goblet cells in the gastrointestinal tract, secrete a viscous material comprised of high molecular weight glycoproteins known as mucins, which when hydrated form mucus. The mucins bind to pathogens, thereby trapping them and washing away potential invaders. In the lower respiratory tract, hairlike, mobile structures called cilia protrude through the epithelial cells and move microbes trapped in the mucus up the tracheobronchial tree and toward the throat. The physiologic responses of coughing and sneezing further aid in their removal from the body.

Microorganisms that are trapped by mucus are then subjected to various chemical defenses present throughout the body. Lysozyme is a hydrolytic enzyme found in tears,
saliva, and human milk, which is capable of cleaving the walls of bacterial cells by hydrolyzing the 1,4 beta-linkages between residues in peptidoglycan. The complement system is found in the blood and is essential for the activity of antibodies. It is comprised of 20 different proteins, many of which act as precursors of enzymes. An antigen–antibody complex initiates this system. Activation of the complement system increases bacteria aggregation, which renders them more susceptible to phagocytosis through activation of mast cells and basophils and through the direct release of lytic complexes that rupture cell membranes of invading organisms (Fig. 13.1). In addition, recent research has shown that complement plays a key role in bridging the innate–adaptive immune responses through the release of C3 and C5 from DCs. In the stomach and intestines, death of microbes results from the action of digestive enzymes, acidic conditions, and secretions of defensins, small cationic peptides that kill within minutes both gram-positive and gram-negative microorganisms by disrupting the microbial membrane.

When pathogens overcome the epithelial defenses, the innate immune response is initiated by the body’s leukocytes by the recognition of common surface receptors present on the invading microorganisms.

**Cells of Innate Immunity**

The cells of the innate immune response are capable of recognizing microbes that share common surface receptor characteristics and in response initiate a broad spectrum of responses that target the invading microorganisms. The key cells of innate immunity include neutrophils, macrophages, DCs, NK cells, and intraepithelial lymphocytes.

**Neutrophils and Macrophages**

The leukocytes involved in the innate immune response are derived from myeloid stem cells and subdivided into two distinct groups based upon the presence or absence of specific staining granules in their cytoplasm. Leukocytes that contain granules are classified as granulocytes and include neutrophils, eosinophils, and basophils. Cells that lack granules are classified as agranulocytes and include lymphocytes, monocytes, and macrophages.

Neutrophils, which are named for their neutral-staining granules, are the most abundant granulocytes found in the body and make up approximately 55% of all white blood cells. They are also known as polymorphonuclear neutrophils (PMNs). They are phagocytic cells and are capable of ameboid-like movement. They function as early responder cells in innate immunity. They are rare in the tissues and in body cavities and lay predominantly dormant in the blood and bone marrow until they are needed in the immune response. Eosinophils have large coarse granules and normally comprise only 1% to 4% of the total white cell count. In contrast to neutrophils, these cells do not ingest cellular debris but rather antigen–antibody complexes and viruses. They frequently become active in parasitic infections and allergic responses. Basophils make up less than 1% of the total white cell count and contain granules that release a multitude of substances including histamine and proteolytic enzymes. There function is not completely understood, but they are believed to play a role in allergy and parasitic infection as well.

The agranulocytes involved in innate immunity are part of the mononuclear phagocyte system (MPS) and include the monocytes and macrophages. Monocytes are the largest in size of all the white blood cells but make up only 3% to 7% of the total leukocyte count. They are released from the bone marrow...
marrow into the bloodstream where they migrate into tissues and mature into macrophages and dendritic cells where they participate in the inflammatory response and phagocytize foreign substances and cellular debris. Macrophages have a long life span, reside in the tissues, and act as the first phagocyte that invading organisms encounter upon entering the host. Neutrophils and macrophages work in concert with each other and are crucial to the host’s defense against all intracellular and extracellular pathogens.

Macrophages are essential for the clearance of bacteria that breach the epithelial barrier in the intestine and other organ systems. They also have remarkable plasticity that allows them to efficiently respond to environmental signals and change their functional characteristics. This makes them more efficient phagocytic cells than the more abundant neutrophils. Once activated, these cells engulf and digest microbes that attach to their cell membrane. The ability of these phagocytic cells to initiate this response is dependent upon the recognition of pathogenic surface structures known as PAMPs (pathogen-associated molecular patterns) that attach to their cell membrane. Phagocytosis of invading microorganisms helps to limit the spread of infection until adaptive immune responses can become fully activated.

In addition to phagocytosis, macrophages and dendritic cells process and present antigens in the initiation of the immune response acting as a major initiator of the adaptive immune response. These cells secrete substances that initiate and coordinate the inflammatory response or activate lymphocytes. Macrophages can also remove antigen–antibody aggregates or, under the influence of T cells, they can destroy malignant host or virus-infected cells.

Dendritic Cells

Dendritic cells (DCs) are specialized, bone marrow–derived leukocytes found in lymphoid tissue and are the bridge between the innate and adaptive immune systems. DCs take their name from the dendrites within the central nervous system because they have surface projections that give them a similar appearance. DCs are relatively rare cells that are found mainly in tissues exposed to external environments such as the respiratory and gastrointestinal systems. They are present primarily in an immature form that is available to directly sense pathogens, capture foreign agents, and transport them to secondary lymphoid tissues. Once activated DCs undergo a complex maturation process in order to function as key antigen-presenting cells (APCs) capable of initiating adaptive immunity. They are responsible for the processing and presentation of foreign antigens to the lymphocytes. DCs, like macrophages, also release several communication molecules that direct the nature of adaptive immune responses.

Natural Killer Cells and Intraepithelial Lymphocytes

NK cells and intraepithelial cells (IELs) are other cell types involved in the innate immune response. NK cells are so named because of their ability to spontaneously kill target organisms. Both types of cells rely on the recognition of specific PAMPs associated with the microorganism cell type.

NK cells are a heterogeneous population of innate lymphocytes that mediate spontaneous cytotoxicity against infected cells. They resemble large granular lymphocytes and are capable of killing some types of tumor and/or infected cells without previous exposure to surface antigens. NK cells were given their name because of their ability to mediate spontaneous cytotoxicity during both innate immune responses. However, they have been shown to play an equally important role in limiting the spread of infection and assisting in the development of adaptive immune responses through the production of cytokines. NK cells assist in dendritic cell maturation and innate immune control of viral infections. These cells are capable of directly killing host cell infected with intracellular (viral) or bacterial pathogenic organisms. They comprise approximately 10% to 15% of peripheral blood lymphocytes but do not bear T-cell receptors (TCR) or cell surface immunoglobulins (Igs). Two-cell surface molecules have been identified, CD16 and CD56, which are widely used to identify NK cell activity. CD16 serves as a receptor for the IgG molecule, which provides NK cells with the ability to lyse IgG-coated target cells.

NK cells can be divided into two main subsets based upon their ability to excrete proinflammatory cytokines. In addition, they differ in their expression of inhibitory versus activating receptors. Cells that express activating receptors (i.e., NKG2D) are induced in response to pathogen-infected or stressed cells, whereas the inhibitory receptors on NK cells recognize patterns (major histocompatibility complex [MHC]-I, lectins) on normal host cells and function to inhibit the action of the NK cells. This assures that only “foreign” cells are destroyed (see Fig. 13.2). In addition to their role as phagocytes, NK cells assist in T-cell polarization, DC maturation, and innate immune control of viral infection through the secretion of immune modulators and antiviral cytokines. Current research is investigating the utilization of these properties of NK cells for the development of vaccines that can modulate and direct the immune response through enhanced cytokine activity.

Pathogen Recognition

The innate immune response plays a crucial role in the proinflammatory response to infection and relies upon the ability of host defenses to differentiate self from nonself so that only invading organisms are targeted. The leukocytes involved in this response recognize certain evolutionarily retained patterns present on the surface of pathogens and in response bind to the membrane and destroy the invading organism through the process of phagocytosis (Fig. 13.3).

Pattern Recognition

Invading pathogens contain conserved structures in their cell membranes termed pathogen-associated molecular patterns (PAMPs), which are recognized by the cells of the innate immune system because they possess a limited number of
germline-encoded pattern recognition receptors (PRRs). Upon PAMP recognition, PRRs come in contact with the cell surface and/or send intracellular signals to the host that trigger proinflammatory and antimicrobial responses including the synthesis and release of cytokines, chemokines, and cell adhesion molecules. The PAMPs recognized by the host PRRs are made up of a combination of sugars, lipid molecules, proteins, or patterns of modified nucleic acids and are essential to the functioning and infectivity of the pathogen. Because the PAMPs are essential for the functioning of the microorganism, mutation cannot help it avoid immune recognition. The human complement of PRRs is very extensive (approximately 1000) so the classes of pathogens recognized by them are very diverse. Therefore, pathogens of very different biochemical composition are recognized by relatively similar mechanisms by host PRRs, and no single class of pathogens is sensed by only one type of PRR. Therefore, the host genetic code allows for the unique receptors involved in both innate and adaptive immunity to recognize fine details of molecular structure.

The ability of the innate immune response to limit microbes early in the infectious process results from the binding of pathogens to the PRRs on leukocytes, which in turn initiates the signaling events that lead to complement activation, phagocytosis, and autophagy. Once initiated, white blood cells, neutrophils, and monocytes migrate from the blood to the tissues, along with other body fluids causing peripheral edema. Blood monocytes mature into macrophages as they traverse the tissues and join the macrophages and DCs already present in the tissues. PRRs present on these cells become activated, which amplifies the inflammatory response through enhanced secretion of all chemical mediators including cytokines and complement.

**Toll-Like Receptors**

The most studied PRRs associated with the innate immune response are the Toll-like receptors (TLRs). TLRs derive their name from the study of the Drosophila melanogaster toll protein, which is responsible for the resistance of Drosophila to bacterial and fungal infections. Structurally, TLRs are integral glycoproteins that possess an extracellular or luminal ligand-binding site containing leucine-rich repeats and a cytoplasmic signaling toll/interleukin-1 (IL-1) domain. Binding of PAMP to a TLR induces a conformational change in the receptor, which subsequently triggers intracellular signal transduction and activation of cellular processes, such as activation of transcription factors such as nuclear factor \(\kappa_B\) (NF-\(\kappa_B\)). NF-\(\kappa_B\) regulates the production of a number of proteins that are important components of innate immunity. TLRs can be found in most of the bone marrow cells including the macrophages, DCs, neutrophils, T cells, B cells, and non–bone marrow cells including epithelial and fibrocytes. Eleven different TLRs have been identified in humans, and they each recognize distinct PAMPs derived from various microorganisms including bacteria, viruses, fungi, and protozoa.

Human TLRs can be divided into subfamilies that primarily recognize related PAMPs. TLR1, TLR2, TLR4, and TLR6 recognize lipids and lipopolysaccharides (LPS), whereas TLR3, TLR7, TLR8, and TLR9 recognize nucleic acids. TLRs can also be classified according to their cellular distribution such that TLR1, TLR2, TLR4, TLR5, TLR6, TLR10, and TLR11 are expressed extracellularly and THOR, TLR7, TLR8, and TLR9 are mainly expressed in intracellular compartments. These receptors are involved in responses to widely divergent types of molecules that are commonly expressed by microbial, but not mammalian, cell types. For example, TLR4 is essential for phagocytic recognition and response to the LPS present in
Inflammatory process including acute-phase proteins, lectins, and complement. Components of the adaptive immune response can also act as opsonins. For example, when the humoral response is activated, IgG and IgM antibodies can coat cellular particles on pathogens and bind to Fc receptors on neutrophils and macrophages, enhancing the phagocytic function of innate cells.

**Inflammatory Cytokines**

Cytokines are low molecular weight proteins that serve as soluble chemical messengers and which mediate the interaction between immune and tissue cells. They are part of an integrated signaling network with extensive functions in both the innate (nonspecific) and adaptive immune defenses. The cytokines involved in innate immunity include TNF-α and lymphotoxin; interferons (IFN-γ, IFN-α, IFN-β); the interleukins IL-1, IL-6, and IL-12; and chemokines (see Table 13.2). These substances modulate innate immunity by stimulating the development of cells involved in both innate and adaptive immunity, producing chemotaxis within leukocytes, stimulating acute-phase protein production, and inhibiting viral replication. Once an innate immune phagocyte is activated via PRR–PAMP with a pathogen, cytokines are released into the surrounding tissues where they exert their effect. If large numbers of cells are activated, then cytokines may be able to stimulate inflammatory processes in tissues far from the initial site of infection. Under normal circumstances, the duration of activity of cytokines is relatively short so that a prolonged immune response does not occur.

Opsonins

Opsonins are molecules that coat negatively charged particles on cell membranes and as a result enhance the recognition and binding of phagocytic cells to microorganisms. The process by which the cellular particles on microbes are coated is called opsonization. Once the opsonin binds to the microbe, it is able to activate the phagocyte after attachment to a PRR on the phagocytic cell. There are several opsonins important in innate immunity and the acute inflammatory process including acute-phase proteins, lectins, and complement. Components of the adaptive immune response can also act as opsonins. For example, when the humoral response is activated, IgG and IgM antibodies can coat cellular particles on pathogens and bind to Fc receptors on neutrophils and macrophages, enhancing the phagocytic function of innate cells.

Soluble Mediators of Innate Immunity

While cells of the innate immune system communicate critical information about invading microorganisms and self–nonself recognition through cell-to-cell contact, soluble mediators are also essential for many other aspects of the innate immune response. Development of innate immune response is very much dependent upon the secretion of soluble molecules such as opsonins, cytokines, and acute-phase proteins.

TNF-α and lymphotoxins are cytokines that are structurally related and that have similar cytotoxic activities. The two cytokines differ in that TNF-α can be secreted by a variety of immune cells, but the lymphotoxins are predominantly secreted by activated lymphocytes and NK cells. These cytokines regulate development of the lymphoid tissues and the inflammatory process through induction of adhesion molecules and other cytokines/chemokines. The IFNs are another family of cytokines that are critically involved in initiating and enhancing the cellular immune response to viral infection of host cells. In addition, they play a key role in amplifying the presentation of antigens to specific T cells. Type I interferon (IFN-α and IFN-β) is secreted by virus-infected cells, while type II, immune or gamma interferon (IFN-γ), is mainly secreted by T cells, NK cells, and macrophages. When activated IFNs interact with specific cellular receptors, causing the expression of antiviral and immune modulatory genes. IFNs activate macrophages, induce B cells to switch Ig type, alter T-helper response, inhibit cell growth, promote apoptosis, and induce an antiviral state in uninfected cells. Finally, ILs help to regulate the immune response by increasing the expression of adhesion molecules on endothelial cells, stimulating migration of leukocytes into infected tissues, and by stimulating the production of antibodies by the cells of the adaptive immune response.

**Acute-Phase Proteins**

Two acute-phase proteins that are involved in the defense against infections are the mannose-binding ligand (MBL) and C-reactive protein (CRP). MBL and CRP are produced in the liver in response to activation of proinflammatory cytokines. MBL binds specifically to mannose residues, and CRP binds to both phospholipids and sugars that are found on the surface of microbes. These substances act as “costimulatory” opsonins and enhance the binding of phagocytic cells to suboptimally opsonized invading microorganisms. They also act as activators of the alternative complement pathway.

**The Complement System**

The complement system is a powerful effector mechanism of both innate and adaptive immunity that allows the body to localize infection and destroy invading microorganisms. The complement system is composed of group of proteins found in the circulation and in various extracellular fluids. The proteins of the complement system normally circulate as inactive precursors. When activated a series of proteolytic and protein–protein interactions is initiated that ultimately culminates in opsonization of invading pathogens, migration of leukocytes to the site of invasion, initiation of a localized inflammatory reaction, and ultimate lysis of the pathogen. The proteins of the complement system are mainly proteolytic enzymes and make up approximately 10% to 15% of the plasma proteins. For a complement reaction to occur, the complement components must be activated in the proper sequence. Inhibitor proteins and the instability of the activated complement proteins at each step of the process prevent uncontrolled activation of the complement system.

There are three parallel but independent pathways that result in activation of the complement system during the innate immune response: the classical, the lectin, and the alternative pathways. The reactions of the complement systems can be divided into three phases:

1. Initiation or activation
2. Amplification of inflammation
3. Membrane attack response

The three pathways differ in the proteins used in the early stage of activation, but all ultimately converge on the key complement protein C3, which is essential for the amplification stage. Activated C3 then activates all subsequent complement molecules (C5 through C9) resulting in the ultimate lysis of cells.

The classic pathway is initiated by an antigen–antibody complex (either IgG or IgM mediated), which causes a specific reactive site on the antibody to be “uncovered” so that it can bind directly to the C1 molecule in the complement system. Once C1 is activated, a “cascade” of sequential reactions is set in motion. Initially a small amount of enzyme is produced, but with activation of successive complement proteins successively increasing, concentrations of proteolytic enzymes are produced. This process is known as amplification. In the lectin or alternative complement pathway, inactive circulating complement proteins are activated when they are exposed to microbial surface polysaccharides, MBL, CRP, and other soluble mediators that are integral to innate immunity. Like the classic pathway, the lectin and alternative pathways create a series of enzymatic reactions that cleave successive complement proteins in the pathway.

During the activation phase of the complement cascade, cleavage of C3 produces C3a and C3b. C3b is a key opsonin that coats bacteria and allows them to be phagocytized after binding to type I complement receptor on leukocytes. The presence of C3a triggers the migration of neutrophils into the tissues to enhance the inflammatory response. Production of C3a, C4a, and C5a also leads to activation of mast cells and basophils causing them to release histamine, heparin, and other substances. These mediators of the inflammatory response increase tissue blood flow and increase localized capillary permeability allowing increased leakage of fluids and protein into the area. In addition, they stimulate changes in the endothelial cells in order to stimulate chemotaxis of neutrophils and macrophages to the site of inflammation. During the late phase of the complement cascade, cleavage of C5 triggers the assembly of a membrane attack complex from the C5 to C9 proteins. The resulting complex creates a tubelike structure, which penetrates the microbial cell membrane allowing the passage of ions, small molecules, and water into the cell, causing the cell to ultimately burst. The multiple and complementary functions of the complement system make it an integral component of innate immunity and inflammation. It also serves as an essential bridge between the innate and humoral responses. Pathophysiological manifestations associated with deficiencies of complement range from increased susceptibility to infection to inflammatory tissue and autoimmune disorders that are the result of impaired activated complement clearance.
The innate immune system is a complex system that works in an organized, rapid, yet nonspecific fashion as the body’s first line of defense against invasion. It is comprised of the epithelial cells of the skin and mucus membranes; phagocytic cells such as the neutrophils, macrophages, and NK cells; and a series of plasma proteins including cytokines, chemokines, and the proteins of the complement system. These defenses exist before the body encounters an invading microorganism and are activated independent of the adaptive humoral response. The epithelial cells of the skin and mucous membranes block the entry of infectious agents and secrete antimicrobial enzymes, proteins, and peptides in an attempt to prevent microorganisms from invading the internal environment.

The phagocytes of the innate immune response engulf and digest infectious agents. They utilize PRRs, which are present on their membranes to recognize and bind broad patterns of molecules (PAMPs) shared by microbes and that are essential for their survival. TLRs are the most studied of all PRRs and are expressed on many of the cells of the innate immune system. TLRs are involved in responses to widely divergent types of molecules that are commonly expressed by microbial but not mammalian cell types.

Development of a healthy innate immune response is dependent not only upon the coordinated activity of the leukocytes but on the secretion of chemical mediators and soluble molecules, such as opsonins, cytokines, acute-phase proteins, and complement. Opsonins bind to and tag microorganisms for more efficient recognition by phagocytes. Activated leukocytes release cytokines that stimulate the migration of leukocytes to the site of inflammation, stimulate production of acute-phase proteins, and enhance phagocytosis.

The complement system is a primary effector system that functions as part of both the innate and adaptive immune responses. It is comprised of a group of proteins that are activated by three distinct but convergent pathways: the classical, the lectin, and the alternative pathways. The primary function of the complement system is the promotion of inflammation and destruction of the microbes.

The adaptive immune system is the final line of defense against infection and is activated once the innate immune response initiates the inflammatory process. In contrast to innate immunity, the adaptive immune response is capable of targeting specific cells or organisms that it recognizes as foreign to the body through activation of various lymphocytes and their products, including antibodies. The lymphocytes involved in adaptive immunity have the unique ability to remember specific pathogen and mount a heightened immune response during repeat exposures. Each exposure results in a more rapid and aggressive response. Substances present on the surface of pathogens or other foreign substances that elicit adaptive immune responses are called antigens. Adaptive immunity involves two distinct but interconnected mechanisms: humoral and cell-mediated responses. Humoral immunity is mediated by B-lymphocyte activation and subsequent antibody production. It is the primary defense against extracellular microbes and toxins. In contrast, cell-mediated immunity involves the activation of specific T lymphocytes (T-helper and T-cytotoxic lymphocytes), which are responsible for the body’s defense against intracellular microbes such as viruses.

**KEY POINTS**

**ADAPTIVE IMMUNITY**

- The adaptive immune response involves a complex series of interactions between components of the immune system and the antigens of a foreign pathogen. It is able to distinguish between self and nonself, recognize and specifically react to large numbers of different microbes and pathogens, and remember the specific agents.
- Humoral immunity consists of protection provided by the B lymphocyte–derived plasma cells, which produce antibodies that travel in the blood and interact with circulating and cell surface antigens, whereas cell-mediated immunity provides protection through cytotoxic T lymphocytes, which protect against virus-infected or cancer cells.

**Antigens**

Antigens, or immunogens, are substances or molecules that are foreign to the body but when introduced trigger the production of antibodies by B lymphocytes leading to the ultimate destruction of the invader. They are usually large macromolecules (>10,000 Da) such as proteins, polysaccharides, lipids, and free nucleic acids. Antigens are recognized by specific receptors present on the surface of lymphocytes and by the antibodies or immunoglobulins secreted in response to the antigen. Antigens can take the form of any foreign substance including bacteria, fungi, viruses, protozoa, parasites, and nonmicrobial agents such as plant pollens, insect venom, and transplanted organs.
The Complement System

The complement system provides one of the major effector mechanisms of both humoral and innate immunity. The system consists of a group of proteins (complement proteins C1 through C9) that are normally present in the plasma in an inactive form. Activation of the complement system is a highly regulated process, involving the sequential breakdown of the complement proteins to generate a cascade of cleavage products capable of proteolytic enzyme activity. This allows for tremendous amplification because each enzyme molecule activated by one step can generate multiple activated enzyme molecules at the next step. Complement activation is inhibited by proteins that are present on normal host cells; thus, its actions are limited to microbes and other antigens that lack these inhibitory proteins.

The reactions of the complement system can be divided into three phases: (1) the initial activation phase, (2) the early-step inflammatory responses, and (3) the late-step membrane attack responses.

Initial Activation Phase

There are three pathways for recognizing microbes and activating the complement system: (1) the alternative pathway, which is activated on microbial cell surfaces in the absence of antibody and is a component of innate immunity; (2) the classical pathway, which is activated by certain types of antibodies bound to antigen and is part of humoral immunity; and (3) the lectin pathway, which is activated by a plasma lectin that binds to mannose on microbes and activates the classical system pathway in the absence of antibody.

Early-Step Inflammatory Responses

The central component of complement for all three pathways is the activation of the complement protein C3 and its enzymatic cleavage into a larger C3b fragment and a smaller C3a fragment. The smaller 3a fragment stimulates inflammation by acting as a chemoattractant for neutrophils. The larger 3b fragment becomes attached to the microbe and acts as an opsonin for phagocytosis. It also acts as an enzyme to cleave C5 into two components: a C5a fragment, which produces vasodilation and increases vascular permeability, and a C5b fragment, which leads to the late-step membrane attack responses.
Antigens possess immunologically active sites called antigenic determinants, or epitopes. These are smaller, discrete components of the antigen that have a unique molecular shape, which can be recognized by and bound to a specific Ig receptor found on the surface of the lymphocyte or by an antigen-binding site of a secreted antibody (Fig. 13.4). It is not unusual for a single antigen to possess several antigenic determinants and, therefore, be capable of stimulating several different T and B lymphocytes. For example, different proteins that comprise the influenza virus may function as unique antigens (A, B, C, H, and N antigens), each of which contains several antigenic determinants. Hundreds of antigenic determinants are found on structures such as the bacterial cell wall.

Low molecular weight molecules (<10,000 Da) may contain antigenic determinants but alone are usually unable to stimulate an immune response. These molecules are known as haptens. When they are complexed with an immunogenic carrier (usually a protein), they function as antigens. Many haptens exist in nature and frequently create problems for humans. Urushiol is a toxin found in the oils on poison ivy that...
is responsible for initiating an allergic reaction. An allergic response to the antibiotic penicillin is an example of a medically important reaction due to hapten–carrier complexes. The penicillin molecule is very small (350 Da) and usually nonantigenic. However, in susceptible people it can complex with carrier proteins in the body, which are then recognized as “foreign” and capable of initiating an antigen–antibody reaction.

**Cells of Adaptive Immunity**

The principal cells of the adaptive immune system are the lymphocytes, APCs, and effector cells.

**Lymphocytes**

Lymphocytes make up approximately 36% of the total white cell count and are the primary cells of the adaptive immune response. They arise from the lymphoid stem cell line in the bone marrow and differentiate into two distinct but interrelated cell types: the B lymphocytes and T lymphocytes. B lymphocytes are responsible for forming the antibodies that provide humoral immunity, whereas T lymphocytes provide cell-mediated immunity. T and B lymphocytes are unique in that they are the only cells in the body capable of recognizing specific antigens present on the surfaces of microbial agents and other pathogens. As a result, adaptive immune processes are organism specific and possess the capacity for memory.

The recognition of specific surface antigens by lymphocytes is made possible because of the presence of specific receptors or antibodies on the surface of B and T lymphocytes. Scientists have been able to identify these specific proteins and correlate them with a specific cellular function. This has led to the development of a classification system for these surface molecules known as the “cluster of differentiation” (CD). The nomenclature for the surface proteins utilizes the letters “CD” followed by a number that specifies the surface proteins that define a particular cell type or stage of cell differentiation and are recognized by a cluster or group of antibodies. The utilization of this nomenclature has spread to other immune cells and cytokines all of which contribute to the acquired immune response.

Leukocytes involved in the innate immune response, such as macrophages and DCs, also play a key role in adaptive immunity because they function as APCs. They are capable of processing complex antigens into epitopes, which are then displayed on their cell membranes in order to activate the appropriate lymphocytes. Functionally, there are two types of immune cells: regulatory cells and effector cells. The regulatory cells assist in orchestrating and controlling the immune response, while effector cells carry out the elimination of the antigen (microbial, nonmicrobial, or toxin). In the body, helper T lymphocytes activate other lymphocytes and phagocytes, while regulatory T cells keep these cells in check so that an exaggerated immune response does not occur. Cytotoxic T lymphocytes, macrophages, and other leukocytes function as effector cells in different immune responses.

While T and B lymphocytes are generated from lymphoid stem cells in the bone marrow, they do not stay there to mature.
body, specific T cells become activated and specific B cells are stimulated to produce antibodies. Once the first encounter occurs, these cells can exactly recognize a particular microorganism or foreign molecule because each lymphocyte is capable of targeting a specific antigen and differentiating the invader from self or from other substances that may be similar to it. Cell-mediated and humoral immunity is capable of responding to millions of antigens each day because there is an enormous variety of lymphocytes that have been programmed and selected during cellular development. Once the invading substance or organism has been removed from the body, the lymphocytes “remember” the presenting antigen and can respond rapidly during the next encounter. These lymphocytes are called “memory” T and B lymphocytes. They remain in the body for a longer period of time than their predecessors and as a result can respond more rapidly on repeat exposure. The immune system usually can respond to commonly encountered microorganisms so efficiently that we are unaware of the response.

B and T lymphocyte activation is triggered by antigen presentation to unique surface receptors (Fig. 13.6). The antigen receptor present on the B lymphocyte consists of membrane-bound Ig molecules that can bind a specific epitope. However, in order for B lymphocytes to produce antibodies, they require the help of specific T lymphocytes, called helper T cells. While the B lymphocytes bind to one determinant (or hapten) on an antigen molecule, the antigen-specific helper T cell recognizes and binds to another determinant known as the “carrier.” The carrier is an APC, which has previously picked up the antigen.

**FIGURE 13.6** Pathway for immune cell participation in an immune response. (APC, antigen-presenting cell; MHC, major histocompatibility complex; TCR, T-cell receptor.)
up the specified antigen. This interaction (B cell–T cell–APC) is restricted by the presence of cellular products genetically encoded by a self-recognition protein, called a major histocompatibility complex (MHC) molecule. This allows the lymphocyte to differentiate between self and foreign peptides.

Once the B and T lymphocytes are activated and amplified by cytokines released as part of the innate response, the lymphocytes divide several times to form populations or clones of cells that continue to differentiate into several types of effector and memory cells. In the adaptive immune response, the effector cells destroy the antigens and the memory cells retain the ability to target antigen during future encounters.

**Major Histocompatibility Complex Molecules**

In order for the adaptive immune response to function properly, it must be able to discriminate between molecules that are native to the body and those that are foreign or harmful to the body. The T lymphocytes are designed to respond to a limitless number of antigens, but at the same time they need to be able to ignore self-antigens expressed on tissues. The MHC molecules enable the lymphocytes to do just this. The MHC is a large cluster of genes located on the short arm of chromosome 6. The complex occupies approximately 4 million base pairs and contains 128 different genes, only some of which play a role in the immune response. The MHC genes are divided in three classes: I, II, and III, based upon their underlying function (Fig. 13.7).

The class I and II MHC genes are responsible for encoding human leukocyte antigens (HLAs), which are proteins found on cell surfaces and define the individual’s tissue type. These molecules are present on the cell surface glycoproteins that form the basis for human tissue typing. Each individual has a unique collection of MHC proteins representing a unique set of polymorphisms. MHC polymorphisms affect immune responses as well as susceptibility to a number of diseases. Because of the number of MHC genes and the possibility of several alleles for each gene, it is almost impossible for any two individuals to have an identical MHC profile.

The class I and II MHC genes also encode proteins that play an important role in antigen presentation. Protein fragments from inside the cell are displayed by MHC complex on the cell surface, allowing the immune system to differentiate between the body’s own tissues and foreign substances. Cells, which present unfamiliar peptide fragments on the cell surface, are attacked and destroyed by the B and T lymphocytes. Class III MHC genes encode for many of the components of the complement system and play an important role in the innate immune process.

The MHC-I complexes contain a groove that accommodates a peptide fragment. T-cytotoxic cells can only become activated if they are presented with a foreign antigen peptide. MHC-I complexes may present degraded viral protein fragments from infected cells. Class II MHC (MHC-II) molecules are found only on phagocytic APCs, immune cells that engulf foreign particles including bacteria and other microbes. This includes the macrophages, DCs, and B lymphocytes, which communicate with the antigen receptor and CD4 molecule on T-helper lymphocytes.

Like class I MHC proteins, class II MHC proteins have a groove or cleft that binds a fragment of antigen. However, these bind fragments from pathogens that have been engulfed and digested during the process of phagocytosis. The engulfed pathogen is degraded into free peptide fragments within cytoplasmic vesicles and then complexed with the MHC-II molecules on the surface of the cells. T-helper cells recognize these complexes on the surface of APCs and become activated.

The first human MHC proteins discovered are called human leukocyte antigens (HLAs) and are so named because they were identified on the surface of white blood cells. HLAs are the major target involved in organ transplant rejection and as a result are the focus of a great deal of research in immunology. Recent analysis of the genes for the HLA molecules has allowed for better understanding of the proteins involved in this response. The classic human MHC-I molecules are divided into types called HLA-A, HLA-B, and HLA-C, and the MHC-II molecules are identified as HLA-DR, HLA-DP, and HLA-DQ (Table 13.3). Multiple alleles or alternative genes can occupy each of the gene loci that encode for HLA molecules. More than 350 possible alleles for the A locus, 650 alleles for the B locus, and 180 alleles for the C locus have been identified. These genes and their expressed MHC molecules are designated by a letter and numbers (*i.e.*, HLA-B27).
HLA genes are inherited as a unit, called a haplotype, because the class I and II MHC genes are closely linked on one chromosome. Since each person inherits one chromosome from each parent, each person has two HLA haplotypes. Tissue typing in forensics and organ transplantation involves the identification of these haplotypes. In organ or tissue transplantation, the closer the matching of HLA types, the greater the probability of identical antigens and the lower the chance of rejection. However, not all people that develop organ rejection after transplantation develop anti-HLA antibodies. Non-HLA target antigens exist including the MHC class I chain-related antigens A (MICA). These antigens are expressed on epithelial cells, monocytes, fibroblasts, and endothelial cells. Therefore, donor-specific antibodies are not detected prior to organ tissue typing prior to transplantation because they are not expressed on the leukocytes tested.

**Antigen-Presenting Cells**

During the adaptive immune response, activation of a T lymphocyte requires the recognition of a foreign peptide (antigen) bound to a self-MHC molecule. This process requires that stimulatory signals be delivered simultaneously to the T lymphocyte by another specialized cell known as an antigen-presenting cell (APC). Therefore, APCs play a key role in bridging the innate and adaptive immune systems through cytokine-driven up-regulation of MHC-II molecules. Cells that function as APCs must be able to express both classes of MHC molecules and include DCs, monocytes, macrophages, and B lymphocytes residing in lymphoid follicles. Under certain conditions, endothelial cells are also able to function as APCs. APCs have been shown to play a key role in the development of autoimmune diseases and atherosclerosis. Activated T lymphocytes appear to be proatherogenic, and in experimental models, APC and T-cell deficiency have been associated with up to an 80% reduction in atherosclerosis.

Macrophages function as a principal APC. They are key cells of the mononuclear phagocytic system and engulf and digest microbes and other foreign substances that gain access to the body. Since macrophages arise from monocytes in the blood, they can move freely throughout the body to the appropriate site of action. Tissue macrophages are scattered in connective tissue or clustered in organs such as the lung (i.e., alveolar macrophages), liver (i.e., Kupffer cells), spleen, lymph nodes, peritoneum, central nervous system (i.e., microglial cells), and other areas. Macrophages are activated during the innate immune response where they engulf and break down complex antigens into peptide fragments. These fragments can then be associated with MHC-II molecules for presentation to cells of the “cell-mediated” response so that self–nonself recognition and activation of the immune response can occur.

DCs are also responsible for presenting processed antigen to activated T lymphocytes. The starlike structure of the DCs provides an extensive surface area rich in MHC-II molecules and other non-HLA molecules important for initiation of adaptive immunity. DCs are found throughout the body in tissues where antigen enters the body and in the peripheral lymphoid tissues. Both DCs and macrophages are capable of “specialization” depending upon their location in the body. For example, Langerhans cells are specialized DCs in the skin, whereas follicular DCs are found in the lymph nodes. Langerhans cells transport antigens found on the skin to nearby lymph nodes for destruction. They are also involved in the development of cell-mediated immune reactions such as allergic type IV contact dermatitis. Finally, DCs are found in the mucosal lining of the bowel and have been implicated in the development of inflammatory bowel diseases such as Crohn disease and ulcerative colitis, where they present antigens to the B and T lymphocytes through the production of proinflammatory cytokines.

**B Lymphocytes and Humoral Immunity**

The humoral immune response is mediated by antibodies, which are produced by the B lymphocytes. The primary functions of the B lymphocytes are the elimination of extracellular microbes and toxins and subsequent “memory” for a heightened response during future encounters. Humoral immunity is more important than cellular immunity in defending against microbes with capsules rich in polysaccharides and lipid toxins because only the B lymphocytes are capable of responding to and producing antibodies specific for many types of these molecules. The T cells, which are the mediators of cellular immunity, respond primarily to surface protein antigens.

B lymphocytes are produced in the bone marrow and are classified according to the MHC-II proteins, Ig, and
Immunoglobulins

Antibodies are protein molecules also known as immunoglobulins. Igs are classified into five different categories based upon their role in the humoral defense mechanisms. The five classes include IgG, IgA, IgM, IgD, and IgE (Table 13.4). The classic structure of Igs is comprised of four polypeptide chains with at least two identical antigen-binding sites (Fig. 13.9). Each Ig is composed of two identical light (L) chains and two identical heavy (H) chains that form a characteristic “Y”-shaped molecule. The “Y” ends of the Ig molecule carry the antigen-binding sites and are called Fab (i.e., antigen-binding) fragments. The tail end of the molecule, which is called the Fc fragment, determines the biologic and functional characteristics of the class of Igs.

The heavy and light chains of the Ig have certain amino acid sequences, which show constant (C) regions and variable (V) regions. The constant regions have sequences of amino acids that vary little among the antibodies of a particular class of Ig and determine the classification of the particular Ig (e.g., IgG, IgE). The constant regions, therefore, determine the effector function of the particular antibody. For example, IgG can tag an antigen for recognition and destruction by phagocytes. In contrast, the amino acid sequences of the variable regions differ from antibody to antibody. They also contain the antigen-binding sites of the particular molecule. The different amino acid sequences found in these binding sites allow this region of the antibody to recognize its complementary epitope (antigen). The variable amino acid sequence determines the shape of the binding site, forming a three-dimensional pocket that is complementary to the specific antigen. When B lymphocytes divide, they form clones that produce antibodies with identical antigen-binding regions. During the course of the immune response, class switching (e.g., from IgM to IgG) can occur, causing the B cell clone to produce one of the different Ig types.

IgG (gamma globulin) is the most abundant of the Igs making up 75% of the total circulating antibodies. It is a large molecule with a molecular weight of approximately 150 kDa.
IgM accounts for approximately 10% of all circulating antibodies. It normally exists as a pentamer with identical heavy chains and identical light chains. Because of its structure, it is an efficient complement fixing Ig and is instrumental in the ultimate lysis of microorganisms. It also functions as an effective agglutinating antibody, capable of clumping organisms for eventual lysis and elimination. IgM is the first antibody to be produced by the developing fetus and by immature B lymphocytes.

and is composed of two different kinds of polypeptide chain. IgG possesses antiviral, antibacterial, and antitoxin properties. It is present in all body fluids, readily enters the tissues, and is capable of crossing the placenta where it confers immunity upon the fetus. Intact IgG functioning requires the help of APCs. It binds to target cells as well as Fc receptors on NK cells and macrophages, leading to lysis of the target cell. There are four subclasses of IgG (i.e., IgG1, IgG2, IgG3, and IgG4) with specificity for certain types of antigens. For example, IgG2 appears to be responsive to bacteria that are encapsulated with a lipopolysaccharide layer, such as *Streptococcus pneumoniae*, *Neisseria gonorrhoeae*, and several strains of *Salmonella*.

IgA possesses a dimeric structure and is the second most common Ig found in serum accounting for approximately 15% of all antibodies. It is primarily a secretory Ig that is found in saliva, tears, colostrum (i.e., first milk of a nursing mother), and bronchial, gastrointestinal, prostatic, and vaginal secretions. Because it is primarily found in secretions, its primary function is in local immunity on mucosal surfaces. IgA prevents the attachment of viruses and bacteria to epithelial cells.

IgM accounts for approximately 10% of all circulating antibodies. It normally exists as a pentamer with identical heavy chains and identical light chains. Because of its structure, it is an efficient complement fixing Ig and is instrumental in the ultimate lysis of microorganisms. It also functions as an effective agglutinating antibody, capable of clumping organisms for eventual lysis and elimination. IgM is the first antibody to be produced by the developing fetus and by immature B lymphocytes.

IgD is a monomer found primarily on the cell membranes of B lymphocytes where it functions as a receptor for antigen. It circulates in the serum in extremely low levels where its function is essentially unknown. IgD on the surface of B lymphocytes contains extra amino acids at C-terminal so that it can successfully anchor to the membrane. It also associates with the Ig-alpha and Ig-beta chains.

IgE is the least common serum IgE because it binds very tightly to the Fc receptors on basophils and mast cells. It is involved in inflammation and allergic responses by causing mast cell degranulation and release of chemical mediators including histamine. IgE is also essential for combating parasitic infections.
Humoral Immunity

Humoral immunity requires the presence of mature B lymphocytes capable of recognizing antigen and which can ultimately mature into antibody-secreting plasma cells. The ultimate response of the antigen–antibody complex formation can take several forms including antigen–antibody complex precipitation, agglutination of pathogens, neutralization of toxins, phagocytosis or lysis of invading organisms, immune cell activation, and complement activation.

Two separate but interrelated responses occur in the development of humoral immunity: a primary and a secondary response (Fig. 13.10). A primary immune response develops when the body encounters the antigen for the first time. The antigen comes in contact with various APCs including macrophages, DCs, and B lymphocytes. The antigen is processed by these cells in association with the MHC-II molecules on the cells surface and then presented to the lymphocytes (i.e., CD4+ T-helper cells) to initiate the immune process. APCs such as macrophages also secrete ILs, which are essential for CD4+ helper T cell activation. The activated CD4+ helper T cells trigger B cells to proliferate and differentiate into clone plasma cells that produce antibody. The primary immune response takes 1 to 2 weeks, but once generated, detectable antibody continues to rise for several more weeks even though the infectious process has resolved. The memory phase or secondary immune response occurs on subsequent exposure to the antigen. During the secondary response, the rise in antibody occurs sooner and reaches a higher level because of available memory cells.

During the primary response, B lymphocytes proliferate and differentiate into antibody-secreting plasma cells. A fraction of the activated B cells do not undergo differentiation but rather remain intact to form a pool of memory B lymphocytes that then become available to efficiently respond to invasion during subsequent exposure. Activated T cells can also generate primary and secondary cell-mediated immune responses and the concurrent development of T memory cells.

The immunization process makes use of the primary and secondary immune responses. The initial vaccination causes production of both plasma cells and memory cells. The plasma cells destroy the invading organism or toxin, and the memory cells provide defense against future exposure. “Booster” immunizations produce an immediate antigen–antibody response that simulates an immediate rise in antibody levels. Current phase I clinical immunization trials for cancer treatment show dense concentrations of CD4+ and CD8+ T lymphocytes and plasma cells in preexisting tumors after vaccination with irradiated malignant cells.

T Lymphocytes and Cellular Immunity

T lymphocytes serve many functions in the immune system including the activation of other T cells and B cells, control of intracellular viral infections, rejection of foreign tissue grafts, activation of autoimmune processes, and activation of delayed hypersensitivity reactions. These processes make up the body’s cell-mediated or cellular immunity. The effector phase of cell-mediated immunity is carried out by T lymphocytes and macrophages.

T lymphocytes arise from lymphoid stem cells in the bone marrow, but unlike B lymphocytes, they migrate to the thymus gland to undergo the process of maturation. The thymus gland is richly innervated and produces several peptide...
hormones such as thymulin and thymopoietin, which are believed to be involved in T-cell maturation. T-cell precursors are attracted to the thymus by thymotaxin, a chemotactic factor secreted by thymic epithelial cells. Once the prothymocyte enters the cortex of the thymus, terminal deoxynucleotidyl transferase (TdT) is expressed causing gene rearrangement and increased TCR diversity. The pre-TCR is expressed, resulting in the formation of a pre-TCR. This facilitates further gene rearrangement, enhances alpha chain gene rearrangement, and causes full maturation and expression of CD4+ (helper) and CD8+ (cytotoxic) lymphocytes. These are the predominant lymphocytes in the body. Mature T lymphocytes leave the thymus and migrate to peripheral lymphoid tissues, where they multiply and differentiate into memory T cells and various other mature lymphocytes upon encountering an antigen.

The TCR on the mature lymphocyte is composed of two polypeptides that fold to form a groove that recognizes processed antigen peptide–MHC complexes. It consists of two transmembrane molecules, the TCR-α and the TCR-β, that are the result of rearrangement of first the TCR-β and then the TCR-α gene. The majority of TCRs recognize antigenic peptides that are bound to MHC-derived molecules. The TCR is associated with several surface molecules such as CD4 and CD8. CD4 is associated with the helper T cell, and CD8 is associated with the cytotoxic T cell. CD4 and CD8 help stabilize the TCR–antigen–MHC complex during T-cell activation. The TCR is also associated with other surface molecules known as the CD3 complex, which also aid in cell signaling.

**Helper T Cells and Cytokines in Adaptive Immunity**

The activation of helper T cells is the central event in the initiation of the humoral and cell-mediated immune response. CD4+ helper T cells (T₄) serve as master regulators for the immune system. They become activated when their TCRs interact with antigens that are complexed with class II MHC on the surface of APCs. Once CD4+ cells are activated, the cytokines they secreted in response influence the function of nearly all other cells of the immune system. Depending upon the specific cytokine that is released by the CD4+ T cell the subsequent immunologic response will be activated. These cytokines are able to activate and regulate B cells, cytotoxic T lymphocytes, NK cells, macrophages, and other immune cells. The first cytokine to be produced by CD4+ T cells after activation is IL-2. IL-2 is necessary for the proliferation and function of helper T cells, cytotoxic T cells, B cells, and NK cells. IL-2 interacts with T lymphocytes by binding to specific membrane receptors that are present on activated T cells but not on resting T cells. T-cell amplification relies on the presence of both IL-2 and IL-2 receptors; if either is missing, cell proliferation ceases. There are other cytokines that are not produced by CD4+, but are essential for its function. IL-1 is produced by inflammatory cells and is responsible for increasing the expression of adhesion molecules on endothelial cells, enabling transmigration of leukocytes, and by stimulating antibody production. Another cytokine essential for CD4+ function is IL-6. IL-6 influences T cell effector functions by promoting helper T cell (TH) differentiation through up-regulation of NFATc2 and c-maf.

The activated CD4+ helper T cell can differentiate into two distinct subpopulations of helper T cells (i.e., T₁H or T₂H) based on the cytokines secreted by the APCs at the site of activation (Table 13.5). Macrophages and DCs produce IL-12, which directs the maturation of CD4+ helper T cells toward the TH₁ subtype, whereas mast cells and T cells produce IL-4, which induces differentiation toward the TH₂ subtype. The TH₁ cells direct B lymphocytes to switch class and produce the IgE antibodies necessary for an allergic or hypersensitivity response. The distinct pattern of cytokine secreted by mature TH₁ and TH₂ cells further defines these subpopulations of TH cells and determines whether a humoral or cell-mediated response will ultimately occur. Activated TH₁ cells produce the cytokines IL-2 and IFN-γ, whereas TH₂ cells produce IL-4 and IL-5. IL-5 is an activator of eosinophils that, along with IgE, functions in the control of helminth (intestinal parasite) infections. Some of the cytokines (e.g., IL-10) made by TH₂ cells are anti-inflammatory and inhibit macrophage activation and suppress other TH₁ responses.

**Regulatory T Cells**

Regulatory T cells (T\(_{\text{R}}\)) are a subset of T lymphocytes that function to control immune system responses. Different populations of T\(_{\text{R}}\) cells produced in the thymus have been identified including those that express CD4 and CD25 on their surface. These cells represent a subset of CD4+ cells that act as “negative regulators” of the immune process\(^{34}\). They suppress immune responses by inhibiting the proliferation of other potentially harmful self-reactive lymphocytes. Production of regulatory T cells is highly dependent upon the presence of antigen, activation of a TCR by the antigen, and the release of the cytokines IL-10 and transforming growth factor-β (TGF-β).\(^{34}\) These cytokines inhibit the proliferation and activation of lymphocytes and macrophages. There is also recent evidence of the existence of regulatory CD8+ T cells that can selectively down-regulate T cells activated by either self or foreign antigens. These cells differentiate into regulatory cells during the primary immune response and function to suppress the secondary immune response. The CD8+ regulators are, therefore, primarily involved in self–nonself discrimination. The ability of the regulatory T cells to control many aspects of the immune response has significant implications for clinical practice. Promise has been shown in the control of inflammatory bowel disease, experimental allergic encephalitis, and autoimmune diabetes.

**Cytotoxic T Cells**

The primary function of cytotoxic T (CD8+) cells is to monitor the activity of all cells in the body and destroy any that threaten the integrity of the body. CD8+ T cells recognize antigens that are presented on the cell surface by MHC class I–derived molecules that sample peptides from protein degradation products from inside cells infected by viruses or transformed by cancer\(^{33}\) (Fig. 13.11). The ability of CD8+ cells to recognize class I MHC–antigen complexes on infected target cells ensures that neighboring uninfected host cells, which express class I MHC molecules alone or with self-peptide, are not indiscriminately destroyed. The CD8+ cytotoxic T lymphocytes destroy target cells by a variety of mechanisms including the release of cytolytic enzymes, toxic cytokines, and pore-forming molecules (i.e., perforins) or by triggering membrane molecules and intracellular apoptosis. Apoptosis is a normal biological process that eliminates excessive, dangerous, or damaged cells from the body. The CD8+ T cells play a large role in controlling replicating viruses and intracellular bacteria because antibody cannot readily penetrate the membrane of living cells.

**Cell-Mediated Immunity**

In order for the cell-mediated immune response to carry out its function, healthy CD4+ and CD8+ T lymphocytes are required. Activated CD4+ helper T cells release various cytokines (i.e., IFN-γ) that recruit and activate other CD8+ cytotoxic T cells, macrophages, and inflammatory cells. Cytokines (e.g., chemokines) stimulate migration of several types of inflammatory cells, including macrophages, neutrophils, and basophils, which further enhances the phagocytic, metabolic, and enzymatic functions of the cell-mediated immune response. This results in a more rapid and more efficient destruction of infected cells. This type of defense is important against many intracellular pathogens such as *Mycobacterium* species and *Listeria monocytogenes* but unfortunately plays a role in delayed hypersensitivity reactions. Allergic contact dermatitis (delayed hypersensitivity type IV) results from the activation of both CD4+ and CD8+ T-cell precursors in the lymph nodes draining the site of antigen presentation. These “haptenated peptides” stimulate the recruitment of T cells at the site of antigen presentation, inducing inflammatory signals and apoptosis of epidermal cells, leading to the development of inflammation, to the release of chemical mediators, and to clinical symptoms.

In cell-mediated immune responses, the actions of T lymphocytes and effector macrophages predominate. The most aggressive and abundant phagocyte, the macrophage, becomes activated after exposure to T-cell cytokines, especially IFN-γ.\(^{35}\) The initial stages of cell-mediated immunity are initiated when an APC displays an antigen peptide–class I or II MHC complex to the CD4+ helper T cell and activates it. The activated helper T cell then synthesizes IL-2, IL-4, and other cytokines, which stimulate increased production of CD4+ helper T cells and then amplify the response. Additional cytokine release enhances the activity of cytotoxic T cells and effector macrophages.

---

**Figure 13.11** Destruction of target cell by cytotoxic T cell. Cytokines released from the activated helper T cell enhance the potential of the cytotoxic T cell in destruction of the target cell.
Lymphoid Organs

The central and peripheral lymphoid organs are responsible for the production, maturation, and storage of large numbers of immune system cells including the B and T lymphocytes. These organs and tissues are widely distributed throughout the body and provide different, but often overlapping, functions (Fig. 13.12). The central lymphoid organs are comprised of the bone marrow and the thymus and are responsible for immune cell production and maturation. The tissues and cells of the peripheral lymphoid system store the cells of the immune system where they function to concentrate and process antigen as well as support cellular processes necessary for development of fully functioning, adaptive immune responses. The peripheral lymphoid tissues are comprised of the lymph nodes, spleen, tonsils, appendix, Peyer patches in the intestine, and mucosa-associated lymphoid tissues in the respiratory, gastrointestinal, and reproductive systems. Networks of lymph channels, blood vessels, and capillaries connect the lymphoid organs and transport immune cells, antigens, and cellular debris throughout the body.

Thymus

The thymus is an elongated, bilobed structure located in the mediastinum above the heart and serves as a specialized immune system organ. Each lobe is surrounded by a connective tissue capsule layer and is divided into lobules. The lobules can be divided into an outer cortex and a central medulla, which play different roles in the process of T-lymphocyte maturation. The outer cortex contains densely packed immature T lymphocytes (thymocytes). The inner medulla is a less dense area of tissue that contains fewer but more histologically mature lymphocytes. The medulla is comprised of Hassall corpuscles but also stores DCs and macrophages (Fig. 13.13).

The thymus is essential to the development of the immune system because it is responsible for the production of mature, immunocompetent T lymphocytes. The thymus is a fully developed organ at birth, weighing approximately 15 to 20 g. It is most active in the neonatal and preadolescent periods. At puberty, when the immune cells are well established in peripheral lymphoid tissues, the thymus begins to atrophy and is replaced by adipose tissue. Nevertheless, residual T-lymphocyte production continues throughout adult life. Precursor T (pre-T) cells enter the thymus as functionally and phenotypically immature T cells. They then mature during different cycles and then move from the cortex to the medulla until they are released into the peripheral lymphoid tissues. Rapid cell division, maturation, and selection occur...
in the cortex under the influence of thymic hormones and cytokines. As the T cells mature, they develop the TCRs that differentiate them from other types of T cells. The majority of the thymocytes die in the cortex during the process of gene rearrangement and maturation because they fail to develop the appropriate receptor types on their cell membranes. Only those T cells capable of recognizing foreign antigen displayed by self-MHC are allowed to mature. This process is called thymic selection. Mature, immunocompetent T-helper and T-cytotoxic cells leave the thymus in 2 to 3 days and enter the peripheral lymphoid tissues through the bloodstream.

**Lymph Nodes**

Lymph nodes are small aggregates of lymphoid tissue located along lymphatic vessels throughout the body. The lymphatic vessels carry lymph, which is a clear sometimes yellow-tinged fluid that contains a variety of white blood cells (predominantly lymphocytes) and transports cellular debris and organisms to the lymph nodes to be removed from the body. Each lymph node processes lymph from a discrete, adjacent anatomic site. Lymph nodes are congregated in the axillae and groin and along the great vessels of the neck, thorax, and abdomen. The lymph nodes receive lymph from the collecting ducts, which ultimately drain into the thoracic duct located in the left side of the chest at the level of the subclavian vein. Lymph nodes have two functions: removal of foreign material from lymph before it enters the bloodstream and serving as centers for proliferation and response of immune cells.

Lymph nodes are bean-shaped, encapsulated tissues, approximately 0.5 to 1 cm in diameter. Lymph enters the node through afferent lymph channels and leaves through the efferent lymph vessels located in the deep indentation of the hilus. Lymphocytes and macrophages move slowly through the lymph nodes so that they have adequate time to engulf microorganisms and interact with circulating antigen. The lymphatic system provides a large surface upon which macrophages and DCs can more easily present antigens to T lymphocytes.

Lymph nodes are divided into three distinct and specialized areas—an outer cortex, a paracortex, and an inner medulla (Fig. 13.14). The T lymphocytes predominate in the paracortex and the B lymphocytes predominate in the follicles and germinal centers of the outer cortex. The T lymphocytes proliferate when antigens enter the paracortex of the lymph node. They then migrate to the outer cortex so that they can interact with B lymphocytes that are stored there. Within the follicles the lymphocytes continue to mature, replicate, and interact with the PACs present in the nodes (macrophages and follicular DCs). Activated B cells then migrate to the medulla of the lymph node, where they complete their maturation into plasma cells. Large quantities of antibodies are then released into the systemic circulation.
**Spleen**

The spleen is a large, ovoid secondary lymphoid organ located high in the left upper quadrant of the abdominal cavity between the diaphragm and the stomach. The spleen filters antigens from the blood and is important in the response to systemic infections. It is divided into two systems: the white pulp and the red pulp. The red pulp is well supplied with arteries and venous sinusoids and is the area where senescent and injured red blood cells are removed. The white pulp contains lymphatic nodules and diffuse lymphoid tissue where concentrated areas of B and T lymphocytes are permeated by macrophages and DCs exist. The lymphocytes (primarily T cells) that surround the central arterioles form the area called the periarterial lymphoid sheath. There is also a diffuse marginal zone that contains the follicles and germinal centers and is rich in B cells. This separates the white pulp from the red pulp and allows lymphocytes to move easily between the blood and the lymphatic tissue. A sequence of activation events similar to that seen in the lymph nodes occurs in the spleen.

**Other Secondary Lymphoid Tissues**

Other secondary lymphoid tissues include the mucosa-associated lymphoid tissues, which are nonencapsulated clusters of lymphoid tissues located around membranes lining the respiratory, digestive, and urogenital tracts. These organ systems constantly came in contact with pathogens and toxins and, therefore, require the presence of immune cells in order to respond to the potential invasion by pathogens and harmful substances. In some tissues, the lymphocytes are organized in loose, nondescript clusters, but in other tissues such as the tonsils, Peyer patches in the intestine, and the appendix, their structure is better organized. These tissues contain all the cellular components (i.e., T cells, B cells, macrophages, and DCs) required to mount an immune response. Immunity at the mucosal layers helps to exclude many pathogens from the body and, as a result, protects the more vital internal structures.

**Active versus Passive Immunity**

The goal of the immune system is to protect the host against invasion by potentially dangerous pathogens, foreign substances, and other sources of harmful antigens. Adaptive immune responses accomplish this goal through the activation of cell-mediated and humoral responses. This type of protection can be induced in one of two ways:

1. After exposure to the offending substance and activation of B and T lymphocytes (active immunity)
2. Through the transfer of antibodies against an antigen directly to the host (passive immunity)

Active immunity is acquired when the host mounts an immune response to an antigen either through the process of vaccination or from environmental exposure. It is called active immunity because it requires the host’s own immune system to develop an immunological response including the development of memory. Active immunity is usually long lasting but requires a few days to weeks after a first exposure to sufficiently develop an appropriate immunological response that culminates in the destruction of the presenting antigen. However, with subsequent exposure the immune system rapidly becomes fully activated because of the presence of memory B and T lymphocytes and circulating antibodies. The process by which active immunity is acquired through the administration of a vaccine is termed immunization. An acquired immune response can improve on repeated exposures to an injected antigen (booster vaccines) or a natural infection.

Passive immunity is immunity transferred from another source. The most common form of passive immunity is that conferred from mother to fetus. During fetal development, maternal IgG antibodies are transferred to the fetus via the placenta. After birth, the neonate also receives IgG antibodies from the mother in breast milk or colostrum. Therefore, infants are provided with some degree of protection from infection for approximately 3 to 6 months, giving their own immune system time to mature. Some protection against infectious disease can also be provided by the administration of IgG pooled from human or animal sources. Passive immunity produces only short-term protection that lasts weeks to months.

**Regulation of the Adaptive Immune Response**

In order for a host organism to remain healthy, the immune system must function properly. A weakened immune response may lead to immunodeficiency, but an inappropriate or excessive response can cause allergic reactions and autoimmune diseases. Therefore, the immune system must be capable of regulating itself. The process by which the body regulates itself is poorly understood but must involve all aspects of the innate and adaptive immune responses.

Each exposure to an antigen elicits a predictable response from the immune system. Once the immune system is activated, the response is amplified until it peaks and eventually subsides. This occurs because the body’s normal immune responses are self-limiting. Once the antigen is destroyed and the action of chemical mediators terminated, the immune response ceases. It is believed that anti-inflammatory cytokines and regulatory T lymphocytes play a role in this process.\(^34\)

Tolerance also plays a role in the self-regulation of the immune response. Tolerance is the ability of the immune system to react to foreign antigens but remain nonreactive to self-antigens. Tolerance to self-antigens protects the body from harmful autoimmune responses. This is exquisitely important in vital organs such as the brain, testes, ovaries, and eyes where immunological damage could be lethal to the organism.

Many autoimmune diseases such as Hashimoto thyroiditis and insulin-dependent diabetes mellitus are caused by impairment in both B and T lymphocyte (specifically cytotoxic lymphocytes) functions resulting in direct cellular damage because the body immune system is no longer capable of distinguishing “self” from “nonsel”\(^35,36\).
Adaptive immunity is comprised of two distinct but interrelated processes: cell-mediated and humoral immunity. Together they respond to foreign antigens, amplify and sustain immunological responses, distinguish self from non-self, and confer "memory" so that a heightened response can be initiated on subsequent exposure to an organism. Antigens are usually substances foreign to the host that can stimulate an immune response. Antigens possess specific antigenic binding sites for the cells of the immune system known as epitopes. Epitopes allow the adaptive immune system to distinguish foreign antigens from normal cellular substances whose destruction would be detrimental to the organism.

The principal cells of the adaptive immune system are the B and T lymphocytes, APCs, and effector cells that are responsible for the elimination of antigens. B lymphocytes differentiate into plasma cells that produce antibodies and provide for the elimination of microbes in the extracellular fluid (humoral immunity) as well as memory cells, which are responsible for the rapid immune response with repeat exposure. T lymphocytes differentiate into regulatory (helper T and regulatory T cells) and effector (cytotoxic T cells) cells. APCs consist of macrophages and DCs that process and present antigen peptides to CD4+ helper T cells.

During cellular maturation, T lymphocytes express specific CD molecules on the cellular surfaces that distinguish between the different cell types and that help determine the cells’ functionality. Regulatory CD4+ helper T cells help to modulate the immune response and are essential for the differentiation of B cells into antibody-producing plasma cells and the differentiation of T lymphocytes into effector CD8+ cytotoxic T cells. The CD8+ cytotoxic cells eliminate intracellular microbes, such as viruses and other pathogens. Cells of both the innate and adaptive immune responses produce cytokines that influence adaptive immune responses. These cytokines function as communication molecules for the B and T lymphocytes, stimulate cellular proliferation and differentiation, and ensure the appropriate development of cytotoxic effector and memory cells.

Essential to the proper functioning of the adaptive immune response are the cell surface MHC molecules that allow the immune system cells to distinguish self from nonself. Class I MHC complexes that are present are body cells other than those of the immune system, interact with cytotoxic T cells, and present degraded viral protein fragments from infected cells for destruction. Class II MHC (MHC-II) complexes are found on immune cells including phagocytic APCs, immune cells that engulf foreign particles such as macrophages and DCs. Class II MHC complexes also aid in cell-to-cell communication between different cells of the immune system.

The cells of the adaptive immune system are present in large numbers in the central and peripheral lymphoid organs. Lymphocytes are produced and undergo maturation in the central lymphoid organs (bone marrow and thymus) and are subsequently stored in the peripheral lymphoid structures (lymph nodes, spleen, mucosa-associated lymphoid tissues in the respiratory, gastrointestinal, and reproductive systems) where they function to concentrate antigen, aid in the processing of antigen, and promote cellular interactions necessary for development of adaptive immune responses.

Adaptive immunity can be acquired actively or passively. Active immunity develops through immunization or by having a disease, while passive immunity develops when the host receiving antibodies or immune cells from another source. An acquired immune response can improve with repeated exposure to an injected antigen or a natural infection.

### Developmental Aspects of the Immune System

After completing this section of the chapter, you should be able to meet the following objectives:

- Explain the transfer of passive immunity from mother to fetus and from mother to infant during breast-feeding.
- Characterize the development of active immunity in the infant and small child.
- Describe the changes in the immune response that occur during the normal aging process.

Development of the immune system begins early in fetal life. The thymus arises from the third branchial arch with the cortex arising from its ectodermal layer and the medulla from the endoderm. Over the next 2 to 3 weeks, lymphoid cells are initiated from the yolk sac and fetal liver and then from the bone marrow to colonize the fetal thymus. Development of the secondary lymphoid organs (i.e., spleen, lymph nodes, and mucosa-associated lymphoid tissues) begins soon after. The secondary lymphoid organs are rather small but well developed at birth and mature rapidly after exposure to microbes during the postnatal period. The thymus is the largest lymphoid tissue in the neonate relative to body size and normally reaches its mature weight by 1 year of age.

### Transfer of Immunity from Mother to Infant

The neonate’s immune system is functionally immature at birth so protection against infection and toxic substances occurs through transfer of maternal IgG antibodies. Maternal IgG antibodies readily cross the placenta during fetal...
development and remain functional in the newborn for the first few months of life providing passive immunity until Ig production is well established in the newborn. IgG is the only class of IgG able to cross the placenta. Maternally transmitted IgG is effective against most microorganisms and viruses that a neonate encounters. The largest amount of IgG crosses the placenta during the last weeks of pregnancy and is stored in fetal tissues. Infants born prematurely may be deficient in maternal antibodies and, therefore, more susceptible to infection. Because of transfer of IgG antibodies to the fetus, an infant born to a mother infected with HIV has a positive HIV antibody test result, although the child may not be infected with the virus.

Cord blood does not normally contain IgM or IgA. If present, these antibodies are of fetal origin and represent exposure to intrauterine infection because maternal IgM and IgA antibodies do not readily cross the placenta. Normally, the neonate begins producing IgM antibodies shortly after birth, as a result of exposure to the immense number of antigens normally found in the surrounding environment. However, this IgM is of lower binding affinity and effective against a limited range of antigens. It has also been demonstrated that premature infants can produce IgM as well as term infants. At approximately 6 days of age, the IgM rises sharply, and this rise continues until approximately 1 year of age, when the adult level is achieved.

Serum IgA normally is not present at birth but detected in the neonate approximately 13 days after birth. The levels of IgA increase during early childhood and reach between 6 and 7 years of age. While maternal IgA is not transferred in utero, it is transferred to the breast-fed infant in colostrum. Since IgA antibodies as associated with mucosal members, these antibodies provide local immunity for the intestinal system during early life.

Immune Response in the Older Adult

As we age, the ability of the immune system to protect the body from pathogenic organisms and environmental toxins declines as a result of an overall decline in immune responsiveness. This results from changes in both cell-mediated and humoral immune responses. As a result, older adults are more susceptible to infections, have more evidence of autoimmune and immune complex disorders, and have a higher incidence of cancer than do younger people. In addition, the immune system of older adults is less likely to respond appropriately to immunization. As a result, older adults have a weakened immune response to vaccination. Older adults also frequently have many comorbid conditions that impair normal immune function and compromise the immune response.

The cause of the altered response in older adults is multifactorial. There is a continued decrease in the size of the thymus gland, which begins during puberty and affects overall T-cell production and function. The size of the thymus diminishes to 15% or less of its maximum size. There may also be a decrease in the number of the lymphocytes in the peripheral lymphoid tissue. The most common finding is a slight decrease in the proportion of T cells to other lymphocytes and a decrease in CD4+ and CD8+ cells.

Aging also produces qualitative changes in lymphocyte function. Lymphocytes seem to exhibit altered responses to antigen stimulation with an increased proportion becoming unresponsive to activation. It appears that the CD4+ T lymphocyte is most severely affected because there is a decreased rate of synthesis of the cytokines that stimulate the proliferation of lymphocytes and expression of the specific receptors that interact with the circulating cytokines. Specifically, IL-2, IL-4, and IL-12 levels decrease in older adults. While actual B-cell function is compromised with age, the range of antigens that can be recognized by the B cells does not change.

IN SUMMARY

Neonates are protected against antigens in early life as a result of passive transfer of maternal IgG antibodies through the placenta and IgA antibodies in colostrum. Many changes occur with aging, but the exact mechanisms are not completely understood.

Inflammation is a response intended to eliminate the initial cause of cell injury, remove the damaged tissue, and generate new tissue. It accomplishes this by destroying, enzymatically digesting, walling off, or otherwise neutralizing the harmful agents such as toxins, foreign agents, or infectious organisms. These processes set the stage for the events that will eventually heal the damaged tissue. Thus, inflammation is intimately interwoven with the repair processes that replace damaged tissue or fill in the residual defects with fibrous scar tissue.

Although first described over 2000 years ago, the inflammatory response has evoked renewed interest during the past several years. As a result, the pathogeneses of multiple diseases are known to be linked to the inflammatory response. In these cases, the inflammatory cascade is triggered to be overly zealous to the point of damaging multiple types of human tissue with autoimmune disorders, such as rheumatoid arthritis. This chapter focuses on the morphologic and functional manifestations of acute and chronic inflammation, tissue repair, and wound healing.

THE INFLAMMATORY RESPONSE

Inflammation is a response intended to eliminate the initial cause of cell injury, remove the damaged tissue, and generate new tissue. It accomplishes this by destroying, enzymatically digesting, walling off, or otherwise neutralizing the harmful agents such as toxins, foreign agents, or infectious organisms. These processes set the stage for the events that will eventually heal the damaged tissue. Thus, inflammation is intimately interwoven with the repair processes that replace damaged tissue or fill in the residual defects with fibrous scar tissue.

Although first described over 2000 years ago, the inflammatory response has evoked renewed interest during the past several years. As a result, the pathogeneses of multiple diseases are known to be linked to the inflammatory response. In these cases, the inflammatory cascade is triggered to be overly zealous to the point of damaging multiple types of human tissue with autoimmune disorders, such as rheumatoid arthritis. This chapter focuses on the morphologic and functional manifestations of acute and chronic inflammation, tissue repair, and wound healing.

THE INFLAMMATORY RESPONSE

After completing this section of the chapter, you should be able to meet the following objectives:

- Describe the vascular changes in an acute inflammatory response.
- Characterize the interaction of adhesion molecules, chemokines, and cytokines in leukocyte adhesion, migration, and phagocytosis, which are part of the cellular phase of inflammation.
- List four types of inflammatory mediators and state their function.
Inflammation is the reaction of vascularized tissues to injury. It is characterized by inflammatory mediators, such as complement, tumor necrosis factor alpha, vascular endothelial growth factor (VEGF), neutrophils, and serum amyloid, and the movement of fluid. Inflammation generally localizes and eliminates microbes, foreign particles, and abnormal cells and paves the way for repair of the injured tissue. Inflammatory conditions are commonly named by adding the suffix -itis to the affected organ or system. For example, appendicitis refers to inflammation of the appendix, pericarditis to inflammation of the pericardium, and neuritis to inflammation of a nerve. More descriptive expressions of the inflammatory process might indicate whether the process was acute or chronic and what type of exudate was formed.

The classic description of inflammation has been handed down through the ages. In the first century AD, the local reaction of injury was described in terms that are now known as the cardinal signs of inflammation. These signs are rubor (redness), tumor (swelling), calor (heat), and dolor (pain). In the second century AD, a fifth cardinal sign, functio laesa (loss of function) was added. In addition to the cardinal signs that appear at the site of injury, systemic or constitutional manifestations (e.g., fever) may occur as chemical mediators (e.g., cytokines) produced at the site of inflammation gain entrance to the circulatory system. The constellation of systemic manifestations that may occur during acute inflammation is known as the acute-phase response.

The degree of the inflammatory response is impacted by multiple factors, such as the duration of the insult, the type of foreign agent, the degree of injury, and the microenvironment. Inflammation can be divided into acute and chronic types. Acute inflammation is of relatively short duration, lasting from a few minutes to several days, and is characterized by the exudation of fluid and plasma components and emigration of leukocytes, predominantly neutrophils, into the extravascular tissues. Chronic inflammation is of a longer duration, lasting for days to years, and is associated with the presence of lymphocytes and macrophages, proliferation of blood vessels, fibrosis, and tissue necrosis. These basic forms of inflammation often overlap, and many factors may influence their course.

**Acute Inflammation**

Acute inflammation is the early (almost immediate) reaction of local tissues and their blood vessels to injury. It typically occurs before adaptive immunity becomes established and is aimed primarily at removing the injurious agent and limiting the extent of tissue damage. Acute inflammation can be triggered by a variety of stimuli, including infections, immune reactions, blunt and penetrating trauma, physical or chemical agents (e.g., burns, frostbite, irradiation, caustic chemicals), and tissue necrosis from any cause.

**Cells of Inflammation**

Acute inflammation involves two major components: the vascular and cellular stages. Many tissues and cells are involved in these reactions, including the endothelial cells that line blood vessels, circulating white blood cells, connective tissue cells (mast cells, fibroblasts, tissue macrophages, and lymphocytes), and components of the extracellular matrix (ECM) (Fig. 14.1). The ECM consists of fibrous proteins (collagen and elastin), adhesive glycoproteins, and proteoglycans. At the biochemical level, the inflammatory mediators, acting together or in sequence, amplify the initial response and influence its evolution by regulating the subsequent vascular and cellular responses.
Understanding Acute Inflammation

Acute inflammation is the immediate and early response to an injurious agent. The response, which serves to control and eliminate altered cells, microorganisms, and antigens, occurs in two phases: (1) the vascular phase, which leads to an increase in blood flow and changes in the small blood vessels of the microcirculation, and (2) the cellular phase, which leads to the migration of leukocytes from the circulation and their activation to eliminate the injurious agent. The primary function of inflammatory response is to limit the injurious effect of the pathologic agent and remove the injured tissue components, thereby allowing tissue repair to take place.

Vascular Phase

The vascular phase of acute inflammation is characterized by changes in the small blood vessels at the site of injury. It begins with momentary vasoconstriction followed rapidly by vasodilation. Vasodilation involves the arterioles and venules with a resultant increase in capillary blood flow, causing heat and redness, which are two of the cardinal signs of inflammation. This is accompanied by an increase in vascular permeability with outpouring of protein-rich fluid (exudate) into the extravascular spaces. The loss of proteins reduces the capillary osmotic pressure and increases the interstitial osmotic pressure. This, coupled with an increase in capillary pressure, causes a marked outflow of fluid and its accumulation in the tissue spaces, producing the swelling, pain, and impaired function that represent the other cardinal signs of acute inflammation. As fluid moves out of the vessels, stagnation of flow and clotting of blood occur. This aids in localizing the spread of infectious microorganisms.
Chapter 14  Inflammation, Tissue Repair, and Wound Healing

Cellular Phase: Leukocyte Margination, Adhesion, and Transmigration

The cellular phase of acute inflammation involves the delivery of leukocytes, mainly neutrophils, to the site of injury so they can perform their normal functions of host defense. The delivery and activation of leukocytes can be divided into the following steps: adhesion and margination, transmigration, and chemotaxis. The recruitment of leukocytes to the precapillary venules, where they exit the circulation, is facilitated by the slowing of blood flow and margination along the vessel surface. Leukocyte adhesion and transmigration from the vascular space into the extravascular tissue is facilitated by complementary adhesion molecules (e.g., selectins, integrins) on the leukocyte and endothelial surfaces. After extravasation, leukocytes migrate in the tissues toward the site of injury by chemotaxis or locomotion oriented along a chemical gradient.

Leukocyte Activation and Phagocytosis

Once at the sight of injury, the products generated by tissue injury trigger a number of leukocyte responses, including phagocytosis and cell killing. Opsonization of microbes (1) by complement factor C3b and antibody facilitates recognition by neutrophil C3b and the antibody Fc receptor. Receptor activation (2) triggers intracellular signaling and actin assembly in the neutrophil, leading to formation of pseudopods that enclose the microbe within a phagosome. The phagosome (3) then fuses with an intracellular lysosome to form a phagolysosome into which lysosomal enzymes and oxygen radicals (4) are released to kill and degrade the microbe.
**Endothelial Cells.** Endothelial cells constitute the single cell–thick epithelial lining of blood vessels. They produce antplatelet and antithrombotic agents that maintain vessel patency and vasodilators and vasoconstrictors that regulate blood flow. Endothelial cells are also key players in the inflammatory response and experience significant pathology in people with inflammatory disorders. Functioning endothelial cells provide a selective permeability barrier to exogenous (microbial) and endogenous inflammatory stimuli, regulate leukocyte extravasation by expression of cell adhesion molecules and receptors, contribute to the regulation and modulation of immune responses through synthesis and release of inflammatory mediators, and regulate immune cell proliferation through secretion of hematopoietic colony-stimulating factors (CSFs). Endothelial cells also participate in the repair process that accompanies inflammation through the production of growth factors that stimulate angiogenesis (formation of new blood vessels) and ECM synthesis. Circulating endothelial cells can be used as a trend indicator of vascular dysfunction in people who have systemic lupus erythematosus (SLE), even in people with SLE who have no diagnosed cardiovascular disease.

**Platelets.** Platelets or thrombocytes are the cell fragments circulating in the blood that are involved in the cellular mechanisms of primary hemostasis. Activated platelets also release a number of potent inflammatory mediators, thereby increasing vascular permeability and altering the chemotactic, adhesive, and proteolytic properties of the endothelial cells. When a platelet undergoes activation, over 300 proteins are released. Although only a relatively small proportion of these have been identified, it appears that a significant number are inflammatory mediators. The association between platelets and inflammatory diseases is highlighted by the number of inflammatory disease processes (e.g., atherosclerosis, migraine headache, SLE) shown to be associated with platelet activation.

**Neutrophils and Monocytes/Macrophages.** The neutrophils and macrophages are phagocytic leukocytes that are present in large numbers and are evident within hours at the site of inflammation. Both types of leukocytes express a number of surface receptors and molecules that are involved in their activation. They include mannose receptors that bind glycoproteins of bacteria; toll-like receptors that respond to different types and components of microbes; cell communication receptors that recognize specific cytokines and chemokines produced in response to infections and tissue injury; cell adhesion molecules that affect leukocyte adhesion; and complement receptors that recognize degraded fragments of complement deposited on the microbial surface (Fig. 14.2).

The neutrophil is the primary phagocyte that arrives early at the site of inflammation, usually within 90 minutes of injury. These leukocytes have nuclei that are divided into three to five lobes. Therefore, they often are referred to as polymorphonuclear neutrophils (PMNs) or segmented neutrophils (segs). A white blood cell identified by distinctive cytoplasmic granules is called a granulocyte. The cytoplasmic granules of the granulocytes, which resist staining and remain a neutral color, contain enzymes and antibacterial material that are used in destroying engulfed microbes and dead tissue. Neutrophils are able to generate oxygen (hydrogen peroxide) and nitrogen products (nitric oxide [NO]) that assist in destroying the engulfed debris.

The neutrophil count in the blood often increases greatly during an inflammatory process, especially with bacterial infections. After being released from the bone marrow, circulating neutrophils have a life span of only approximately 10 hours and therefore must be constantly replaced if their numbers are to remain adequate. This requires an increase in circulating white blood cells, a condition called leukocytosis, which is frequently elevated with bacterial infections and tissue injury. With excessive demand for phagocytes, immature forms of neutrophils are released from the bone marrow. These immature cells often are called bands because of the horseshoe shape of their nuclei.

Circulating monocytes, which have a single kidney-shaped nucleus and are the largest of the circulating leukocytes, constitute 3% to 8% of the white blood cell count. The monocytes are released from the bone marrow to act as macrophages. Mononuclear cells arrive at the inflammatory site shortly after the neutrophils and perform their phagocytic functions for several days. Monocytes and macrophages produce potent vasoactive mediators, including prostaglandins and leukotrienes, platelet-activating factor (PAF), inflammatory cytokines, and growth factors that promote regeneration of tissues. The macrophages engulf larger and greater quantities of foreign material than the neutrophils. These longer-lived phagocytes help to destroy the causative agent, aid in the signaling processes of immunity, serve to resolve the inflammatory process, and contribute to initiation of the healing processes. They also play an important role in chronic inflammation, where they can surround and wall off foreign material that cannot be digested.

**Eosinophils, Basophils, and Mast Cells.** Eosinophils, basophils, and mast cells produce lipid mediators and cytokines that induce inflammation. Although all three-cell types have unique characteristics, they all contain cytoplasmic granules that induce inflammation. They are particularly important in inflammation associated with immediate hypersensitivity reactions and allergic disorders.

Eosinophils circulate in the blood and are recruited to tissues, similar to neutrophils. These granulocytes increase in the blood during allergic reactions and parasitic infections. The granules of eosinophils, which stain red with the acid dye eosin, contain a protein that is highly toxic to large parasitic worms that cannot be phagocytized. They also play an important role in allergic reactions by controlling the release of specific chemical mediators.

Basophils are blood granulocytes with structural and functional similarities to mast cells of the connective tissue.
Vascular Stage

The vascular changes that occur with inflammation involve the arterioles, capillaries, and venules of the microcirculation. These changes begin soon after injury and are characterized by vasodilation, changes in blood flow, increased vascular permeability, and leakage of fluid into the extravascular tissues. They are derived from bone marrow progenitors and circulate in blood. The granules of the basophils, which stain blue with a basic dye, contain histamine and other bioactive mediators of inflammation. Both basophils and mast cells bind an antibody, immunoglobulin E (IgE), secreted by plasma cells through receptors on their cell surface. Binding of IgE triggers release of histamine and vasoactive agents from the basophil granules.

Mast cells derive from the same hematopoietic stem cells as basophils but do not develop until they leave the circulation and lodge in tissue sites. Activation of mast cells results in release of preformed contents of their granules (histamine, proteoglycans, proteases, and cytokines such as tumor necrosis factor-α [TNF-α] and interleukin [IL]-16), synthesis of lipid mediators derived from cell membrane precursors (arachidonic acid metabolites, such as prostaglandins, and PAF), and stimulation of cytokine and chemokine synthesis by other inflammatory cells such as monocytes and macrophages. Mast cells are involved in IgE-triggered reactions and with helminth infections.

Vascular Response Patterns. Depending on the severity of injury, the vascular changes that occur with inflammation follow one of three patterns of responses. The first pattern is an immediate transient response, which occurs with minor injury. It develops rapidly after injury and is usually reversible and of short duration (15 to 30 minutes). Typically, this type of leakage affects venules 20 to 60 µm in diameter, leaving capillaries

redness (erythema) and warmth associated with acute inflammation. Vasodilation is induced by the action of several mediators, such as histamine and NO.

Vasodilation is quickly followed by increased permeability of the microvasculature, with the outpouring of a protein-rich fluid (exudate) into the extravascular spaces. The loss of fluid results in an increased concentration of blood constituents (red cells, leukocytes, platelets, and clotting factors), stagnation of flow, and clotting of blood at the site of injury. This aids in localizing the spread of infectious microorganisms. The loss of plasma proteins reduces the intracapillary osmotic pressure and increases the osmotic pressure of the interstitial fluid, causing fluid to move into the tissues and produce the swelling (i.e., edema), pain, and impaired function that are the cardinal signs of acute inflammation. The exudation of fluid into the tissue spaces also serves to dilute the offending agent.

The increased permeability characteristic of acute inflammation results from formation of endothelial gaps in the venules of the microcirculation. Binding of the chemical mediators to endothelial receptors causes contraction of endothelial cells and separation of intercellular junctions. This is the most common mechanism of vascular leakage and is elicited by histamine, bradykinin, leukotrienes, and many other classes of chemical mediators.

FIGURE 14.2 • Leukocyte activation. Different classes of leukocyte cell surface receptors recognize different stimuli. The receptors initiate responses that mediate the functions of the leukocytes.
and arterioles unaffected. Although the precise mechanism for restriction of this effect to the venules is unknown, it may reflect the greater density of receptors in the endothelium of the venules. It has also been suggested that the later leukocyte events of inflammation (i.e., adhesion and emigration) also occur predominantly in the venules of most organs.

The second pattern is an immediate sustained response, which occurs with more serious types of injury and continues for several days. It affects arterioles, capillaries, and venules and is generally due to direct damage of the endothelium. Neutrophils that adhere to the endothelium may also injure endothelial cells.

The third pattern is a delayed hemodynamic response, in which the increased permeability occurs in the venules and capillaries. A delayed response often accompanies injuries due to radiation, such as sunburn. The mechanism of the leakage is unknown, but it may result from the direct effect of the injurious agent, leading to delayed endothelial cell damage.

**Cellular Stage**

The cellular stage of acute inflammation is marked by changes in the endothelial cells lining the vasculature and movement of phagocytic leukocytes into the area of injury or infection. Although attention has been focused on the recruitment of leukocytes from the blood, a rapid response also requires the release of chemical mediators from tissue cells (mast cells, leukocytes from the blood) that are prepositioned in the tissues. The sequence of events in the cellular response to inflammation includes leukocyte

1. Margination and adhesion to the endothelium
2. Transmigration across the endothelium
3. Chemotaxis
4. Activation and phagocytosis

**Margination, Adhesion, and Transmigration.** During the early stages of the inflammatory response, the leukocytes are concentrated along the endothelium wall. Cross-talk between the blood leukocytes and the vascular endothelium defines a definite inflammatory event and ensures secure adhesion and arrest of the leukocytes along the endothelium. As a consequence, the leukocytes slow their migration, adhere tightly to the endothelium, and begin to move along the periphery of the blood vessels. This process of leukocyte accumulation is called margination. The subsequent release of cell communication molecules called cytokines causes the endothelial cells lining the vessels to express cell adhesion molecules, such as selectins, that bind to carbohydrates on the leukocytes. This interaction slows their flow and causes the leukocytes to move along the endothelial cell surface with a rolling movement, finally coming to rest and adhering strongly to intercellular adhesion molecules (ICAMs), thus, attaching on the endothelium. The adhesion causes the endothelial cells to separate, allowing the leukocytes to extend pseudopodia and transmigrate through the vessel wall and then, under the influence of chemotactic factors, migrate into the tissue spaces.

Several families of adhesion molecules, including selectins, integrins (VLA-5), and the immunoglobulin superfamily, are involved in leukocyte recruitment. The selectins are a family of three closely related proteins (P-selectin, E-selectin, and L-selectin) that differ in their cellular distribution but all function in adhesion of leukocytes to endothelial cells. The integrin superfamily consists of 30 structurally similar proteins that promote cell-to-cell and cell-to-ECM interactions. The name integrin derives from the hypothesis that they coordinate (integrate) signals of extracellular ligands with cytoskeleton-dependent motility, shape change, and phagocytic responses of immune cells. Adhesion molecules of the immunoglobulin superfamily include ICAM-1, ICAM-2, and vascular adhesion molecule (VCAM)-1, all of which interact with integrins on leukocytes to mediate their recruitment.

**Chemotaxis.** Chemotaxis is the dynamic and energy-directed process of directed cell migration. Once leukocytes exit the capillary, they wander through the tissue guided by a gradient of secreted chemoattractants, such as chemokines, bacterial and cellular debris, and protein fragments generated from activation of the complement system (e.g., C3a, C5a). Chemokines, an important subgroup of chemotactic cytokines, are small proteins that direct the trafficking of leukocytes during the early stages of inflammation or injury. Several immune (e.g., macrophages) and nonimmune cells secrete these chemoattractants to ensure the directed movement of leukocytes to the site of infection.

**Leukocyte Activation and Phagocytosis.** During the final stage of the cellular response, monocytes, neutrophils, and tissue macrophages are activated to engulf and degrade the bacteria and cellular debris in a process called phagocytosis. Phagocytosis involves three distinct steps: (1) recognition and adherence, (2) engulfment, and (3) intracellular killing. Phagocytosis is initiated by the recognition and binding of particles by specific receptors on the surface of phagocytic cells. This binding is essential for trapping the agent, which triggers engulfment and activates the killing potential of the cell. Microbes can be bound directly to the membrane of phagocytic cells by several types of pattern recognition receptors (e.g., toll-like and mannose receptors) or indirectly by receptors that recognize microbes coated with carbohydrate-binding lectins, antibody, or complement. The coating of an antigen with antibody or complement to enhance binding is called opsonization. Receptor-mediated endocytosis is triggered by opsonization and binding of the agent to phagocyte cell surface receptors. Endocytosis is accomplished through cytoplasmic extensions (pseudopods) that surround and enclose the particle in a membrane-bounded phagocytic vesicle or phagosome. Once inside the cell cytoplasm, the phagosome merges with a cytoplasmic lysosome containing antibacterial molecules and enzymes that can kill and digest the microbe.

Intracellular killing of pathogens is accomplished through several mechanisms, including toxic oxygen and
nitrogen products, lysozymes, proteases, and defensins. The metabolic burst pathways that generate toxic oxygen and nitrogen products (i.e., NO, hydrogen peroxide, and hypochlorous acid) require oxygen and metabolic enzymes such as myeloperoxidase, nicotinamide adenine dinucleotide phosphate (NADPH) oxidase, and NO synthetase. Oxygen-independent pathways generate several types of digestive enzymes and antimicrobial molecules (e.g., defensins). Individuals born with genetic defects in some of these enzymes have immunodeficiency conditions that make them susceptible to repeated bacterial infection.

**Inflammatory Mediators**

Although inflammation is precipitated by infection and injury, its signs and symptoms are produced by chemical mediators. Mediators can originate either from the plasma or from cells (Fig. 14.3). The plasma-derived mediators, which are synthesized in the liver, include the coagulation factors and the complement proteins. These mediators are present in the plasma in a precursor form that must be activated by a series of proteolytic processes to acquire their biologic properties. Cell-derived mediators are normally sequestered in intracellular granules that need to be secreted (e.g., histamine from mast cells) or are newly synthesized (e.g., cytokines) in response to a stimulus. Although the major sources of these mediators are platelets, neutrophils, monocytes/macrophages, and mast cells, endothelial cells, smooth muscle, fibroblasts, and most epithelial cells can be induced to produce some of the mediators.

The production of active mediators is triggered by microbes or host proteins, such as those of the complement, kinin, or coagulation systems, that are themselves activated by microbes or damaged tissues. Mediators can act on one or a few target cells, have diverse targets, or have differing effects on different types of cells. Once activated and released from the cell, most mediators are short-lived. They may be transformed into inactive metabolites, inactivated by enzymes, or otherwise scavenged or degraded.

Inflammatory mediators can be classified by function: (1) those with vasoactive and smooth muscle–constricting properties such as histamine, arachidonic acid metabolites (prostaglandins and leukotrienes), and PAF; (2) plasma proteases that activate members of the complement system, coagulation factors of the clotting cascade, and vasoactive peptides of the kinin system; (3) chemotactic factors such as complement fragments and chemokines; and (4) reactive molecules and cytokines liberated from leukocytes, which when released into the extracellular environment can affect the surrounding tissue and cells.

**Figure 14.3** • Plasma- and cell-derived mediators of acute inflammation.
Histamine. Histamine is present in preformed stores in cells and is therefore among the first mediators to be released during an acute inflammatory reaction. Preformed histamine is widely distributed in tissues, the highest concentrations being found in the connective tissues adjacent to blood vessels. It is also found in circulating blood platelets and basophils. Preformed histamine is found in mast cell granules and is released in response to a variety of stimuli, including trauma and immune reactions involving binding of IgE antibodies. Histamine causes dilation of arterioles and increases the permeability of venules. It acts at the level of the microcirculation by binding to histamine type 1 (H1) receptors on endothelial cells and is considered the principal mediator of the immediate transient phase of increased vascular permeability in the acute inflammatory response. Antihistamine drugs (H1 receptor antagonists), which bind to the H1 receptors, act competitively to antagonize many of the effects of the immediate inflammatory response.

Arachidonic Acid Metabolites. Arachidonic acid is a 20-carbon unsaturated fatty acid found in phospholipids of cell membranes. Release of arachidonic acid by phospholipases initiates a series of complex reactions that lead to the production of the eicosanoid family inflammatory mediators (prostaglandins, leukotrienes, and related metabolites). Eicosanoid synthesis follows one of two pathways: the cyclooxygenase pathway, which culminates in the synthesis of prostaglandins, and the lipoxygenase pathway, which culminates in the synthesis of the leukotrienes (Fig. 14.4).16

Through the cyclooxygenase metabolic pathway, many prostaglandins are synthesized from arachidonic acid.10 The prostaglandins (e.g., PGD2, PGE2, PGF2α, and PGI2) induce inflammation and potentiate the effects of histamine and other inflammatory mediators. The prostaglandin thromboxane A2 promotes platelet aggregation and vasoconstriction. Aspirin and the nonsteroidal anti-inflammatory drugs (NSAIDs) reduce inflammation by inactivating the first enzyme in the cyclooxygenase pathway for prostaglandin synthesis.

Like the prostaglandins, the leukotrienes are formed from arachidonic acid, but through the lipoxygenase pathway. Histamine and leukotrienes are complementary in action in that they have similar functions. Histamine is produced rapidly and transiently while the more potent leukotrienes are being synthesized. The leukotrienes also have been reported to affect the permeability of the postcapillary venules, the adhesion properties of endothelial cells, and the extravasation and chemotaxis of neutrophils, eosinophils, and monocytes. Leukotrienes (LT) C4, LTD4, and LTE4, collectively known as the slow-reacting substance of anaphylaxis (SRS-A), cause slow and sustained constriction of the bronchioles and are important inflammatory mediators in bronchial asthma and anaphylaxis.

Dietary modification of the inflammatory response through the use of omega-3 polyunsaturated fatty acids, specifically eicosapentaenoic acid and docosahexaenoic acid, which are present in oily fish and fish oil may be effective in preventing some negative manifestations of inflammation.16–18 Alpha-linolenic acid, which is present in flaxseed, canola oil, green leafy vegetables, walnuts, and soybeans, is another source of
omega-3 fatty acid. The omega-3 polyunsaturated fatty acids, which are considered antithrombotic and anti-inflammatory, are structurally different from the prothrombotic and proinflammatory omega-6 polyunsaturated fatty acids, which are present in most seeds, vegetable oils, and meats. Typically, the cell membranes of inflammatory cells contain high proportions of omega-6 arachidonic acid, which is the source of prostaglandin and leukotriene inflammatory mediators. Eating oily fish and other foods that are high in omega-3 fatty acids results in partial replacement of arachidonic acid in inflammatory cell membranes by eicosapentaenoic acid, a change that leads to decreased production of arachidonic acid–derived inflammatory mediators. This response alone is a potentially beneficial effect of omega-3 fatty acids. However, omega-3 fatty acids have a number of other effects that might occur downstream of altered eicosanoid production or might be independent of this function. For example, animal and human research has shown that dietary fish oil results in suppressed production of proinflammatory cytokines and decreased expression of adhesion molecules that participate in the inflammatory response.

Platelet-Activating Factor. PAF, which is generated from a complex lipid stored in cell membranes, affects a variety of cell types and induces platelet aggregation. It activates neutrophils and is a potent eosinophil chemoattractant. When injected into the skin, PAF causes a wheal-and-flare reaction and the leukocyte infiltrate characteristic of immediate hypersensitivity reactions. When inhaled, PAF causes bronchospasm, eosinophil infiltration, and nonspecific bronchial hyperreactivity.

Plasma Proteins. A number of phenomena in the inflammatory response are mediated by plasma proteins that belong to three interrelated systems, the clotting, complement, and kinin systems.

The clotting system contributes to the vascular phase of inflammation, mainly through fibrinopeptides that are formed during the final steps of the clotting process. The protease thrombin, which binds to receptors called protease-activated receptors (PARs), provides the final link between the coagulation system and inflammation.10 Engagement of the so-called type 1 receptor (PAR-1) by proteases, particularly thrombin, triggers several responses that induce inflammation, including production of chemokines, expression of endothelial adhesion molecules, induction of prostanoid synthesis, and production of PAF.

The complement system consists of 20 component proteins (and their cleavage products) that are found in greatest concentration in the plasma. The complement proteins are present in inactive forms in the plasma. Many of them are activated to become proteolytic enzymes that degrade other complement proteins, thus forming a cascade that plays an important role in both immunity and inflammation.20–22 The complement proteins assist the inflammatory cascade by increasing vascular permeability, improving phagocytosis, and causing vasodilation.

The kinin system generates vasoactive peptides from plasma proteins called kininogens, by the action of proteases called kallikreins.10 Activation of the kinin system results in release of bradykinin, which increases vascular permeability and causes contraction of smooth muscle, dilation of blood vessels, and pain when injected into the skin. These effects are similar to those of histamine. The action of bradykinin is short-lived, because it is quickly inactivated by an enzyme called kininase. Any bradykinin that escapes inactivation by the kininase enzyme is degraded by the angiotensin-converting enzyme in the lung.10

Cytokines and Chemokines. Cytokines are proteins produced by many cell types (principally activated macrophages and lymphocytes but also endothelium, epithelium, and connective tissue types) that modulate the function of other cells.1,12,23 Although well known for their role in immune responses, these products also play important roles in both acute and chronic inflammation.

Tumor necrosis factor-α and IL-1 are two of the major cytokines that mediate inflammation. The major cellular source of TNF-α and IL-1 is activated macrophages (Fig. 14.5). IL-1 is also produced by many cell types other than macrophages, including neutrophils, endothelial cells, and epithelial cells

![Image](https://example.com/image.png)

**FIGURE 14.5** • Central role of interleukin (IL)-1 and tumor necrosis factor (TNF-α) in the acute inflammatory response. Lipopolysaccharide (LPS) and interferon (IFN)-γ activate macrophages to release inflammatory cytokines, principally IL-1 and TNF-α, responsible for directing both local and systemic inflammatory responses. (ACTH, adrenocorticotropic hormone.) (From Rubin R., Strayer D. E. (Eds.) (2012). Rubin’s pathology: Clinicopathologic foundations of medicine (6th ed., p. 60). Philadelphia, PA: Lippincott Williams & Wilkins.)
Although all acute inflammatory reactions are characterized by vascular changes and leukocyte infiltration, the severity of the reaction, its specific cause, and the site of involvement introduce variations in its manifestations and clinical correlates. These manifestations can range from swelling and the formation of exudates to abscess formation or ulceration.

Characteristically, the acute inflammatory response involves the production of exudates. These exudates vary in terms of fluid type, plasma protein content, and the presence or absence of cells. They can be serous, hemorrhagic, fibrinous, membranous, or purulent. Often the exudate is composed of a combination of these types. Serous exudates are watery fluids low in protein content that result from plasma entering the inflammatory site. Hemorrhagic exudates occur when there is severe tissue injury that damages blood vessels or when there is significant leakage of red cells from the capillaries. Fibrinous exudates contain large amounts of fibrinogen and form a thick and sticky meshwork, much like the fibers of a blood clot. Membranous or pseudomembranous exudates develop on mucous membrane surfaces and are composed of necrotic cells enmeshed in a fibropurulent exudate.

A purulent or suppurative exudate contains pus, which is composed of degraded white blood cells, proteins, and tissue debris. Certain microorganisms, such as Staphylococcus, are more likely to induce localized suppurative inflammation than others. An abscess is a localized area of inflammation containing a purulent exudate that may be surrounded by a neutrophil layer (Fig. 14.6). Fibroblasts may eventually enter the area and wall off the abscess. Because antimicrobial agents cannot penetrate the abscess wall, surgical incision and drainage may be required to effect a cure.

An ulceration refers to a site of inflammation where an epithelial surface (e.g., skin or gastrointestinal epithelium) has become necrotic and eroded, often with associated subepithelial inflammation. Ulceration may occur as the result of traumatic injury to the epithelial surface (e.g., peptic ulcer) or because of vascular compromise (e.g., foot ulcers associated with diabetes).
Chronic inflammation also involves the proliferation of fibroblasts instead of exudates. As a result, the risk of scarring and deformity usually is greater than in acute inflammation. Agents that evoke chronic inflammation typically are low-grade, persistent infections or irritants that are unable to penetrate deeply or spread rapidly. Among the causes of chronic inflammation are foreign bodies such as talc, silica, asbestos, and surgical suture materials. Many viruses provoke chronic inflammatory responses, as do certain bacteria, fungi, and larger parasites of moderate to low virulence. Examples are the tubercle bacillus and the treponeme of syphilis. The presence of injured tissue such as that surrounding a healing fracture also may incite chronic inflammation. Immunologic mechanisms are thought to play an important role in chronic inflammation. The two patterns of chronic inflammation are a nonspecific chronic inflammation and granulomatous inflammation.

Nonspecific Chronic Inflammation

Nonspecific chronic inflammation involves a diffuse accumulation of macrophages and lymphocytes at the site of injury. Ongoing chemotaxis causes macrophages to infiltrate the inflamed site, where they accumulate owing to prolonged survival and immobilization. These mechanisms lead to fibroblast proliferation, with subsequent scar formation that in many cases replaces the normal connective tissue or the functional parenchymal tissues of the involved structures. For example, scar tissue resulting from chronic inflammation of the bowel causes narrowing of the bowel lumen.

Granulomatous Inflammation

A granulomatous lesion is a distinctive form of chronic inflammation. A granuloma typically is a small, 1- to 2-mm lesion in which there is a massing of macrophages and lymphocytes at the site of injury. These modified macrophages resemble epithelial cells and sometimes are called epithelioid cells. Like other macrophages, the epithelioid cells are derived originally from blood monocytes. Granulomatous inflammation is associated with foreign bodies such as splinters, sutures, silica, and asbestos and with microorganisms that cause tuberculosis, syphilis, sarcoidosis, deep fungal infections, and brucellosis. These types of agents have one thing in common: they are poorly digested and usually are not easily controlled by other inflammatory mechanisms. The epithelioid cells in granulomatous inflammation may clump in a mass or coalesce, forming a multinucleated giant cell that attempts to surround the foreign agent (Fig. 14.7). A dense membrane of connective tissue eventually encapsulates the lesion and isolates it. These cells are often referred to as foreign body giant cells.

Systemic Manifestations of Inflammation

Under optimal conditions, the inflammatory response remains confined to a localized area. In some cases, however, local injury can result in prominent systemic manifestations as

![Diagram of inflammatory process](image-url)
inflammatory mediators are released into the circulation. The most prominent systemic manifestations of inflammation include the acute-phase response, alterations in white blood cell count, and fever. Localized acute and chronic inflammation may extend to the lymphatic system and lead to a reaction in the lymph nodes that drain the affected area.

**Acute-Phase Response**

Along with the cellular responses that occur during the inflammatory response, a constellation of systemic effects called the *acute-phase response* occurs. The acute-phase response, which usually begins within hours or days of the onset of inflammation or infection, includes changes in the concentrations of plasma proteins (i.e., acute-phase proteins), skeletal muscle catabolism, negative nitrogen balance, elevated erythrocyte sedimentation rate (ESR), and increased numbers of leukocytes. These responses are generated by the release of cytokines, particularly IL-1, IL-6, and TNF-α. These cytokines affect the thermoregulatory center in the hypothalamus to produce fever, the most obvious sign of the acute-phase response. IL-1 and other cytokines induce an increase in the number and immaturity of circulating neutrophils by stimulating their production in the bone marrow. Other manifestations of the acute-phase response include anorexia, somnolence, and malaise, probably because of the actions of IL-1 and TNF-α on the central nervous system. The metabolic changes, including skeletal muscle catabolism, provide amino acids that can be used in the immune response and for tissue repair. In general, the acute-phase response serves to coordinate the various changes in body function to enable an optimal host response.

In severe bacterial infections (sepsis), the large quantities of microorganisms in the blood result in an uncontrolled inflammatory response with the production and release of enormous quantities of inflammatory cytokines (most notably IL-1 and TNF-α) and development of what is referred to as the *systemic inflammatory response syndrome*.25 These cytokines cause generalized vasodilation, increased vascular permeability, intravascular fluid loss, myocardial depression, and circulatory shock.

**Acute-Phase Proteins.** During the acute-phase response, the liver dramatically increases the synthesis of acute-phase proteins such as fibrinogen, C-reactive protein (CRP), and serum amyloid A protein (SAA).1 The synthesis of these proteins is upregulated by cytokines, especially TNF-α, IL-1 (for SAA), and IL-6 (for fibrinogen and CRP).

CRP was named because it precipitated with the C fraction (C-polypeptide) of pneumococci. The function of CRP is thought to be protective, in that it binds to the surface of invading microorganisms and targets them for destruction by complement and phagocytosis.26 Although everyone maintains a low level of CRP, this level rises when there is an acute inflammatory response.26 Recent interest has focused on the use of high-sensitivity CRP (hsCRP) as a marker for increased risk of myocardial infarction in persons with coronary heart disease.26 It is believed that inflammation involving atherosclerotic plaques in coronary arteries may predispose to thrombosis and myocardial infarction.26

During the acute-phase response, SAA protein replaces apolipoprotein A, a component of high-density lipoprotein (HDL) particles; this presumably increases the transfer of HDL from liver cells to macrophages, which can then use these particles for energy. The rise in fibrinogen causes red cells to form stacks (rouleaux) that sediment more rapidly than do individual erythrocytes. This is the basis for the accelerated ESR that occurs in disease conditions characterized by a systemic inflammatory response.

**White Blood Cell Response**

Leukocytosis, or increased white blood cells, is a frequent sign of an inflammatory response, especially one caused by bacterial infection. The white blood cell count commonly increases from a normal value of 4000 to 10,000 cells/µL to 15,000 to 20,000 cells/µL in acute inflammatory conditions. After being released from the bone marrow, circulating neutrophils have a life span of only about 10 hours and therefore must be constantly replaced if their numbers are to be adequate. With excessive demand for phagocytes, immature forms of neutrophils (bands) are released from the bone marrow.

Bacterial infections produce a relatively selective increase in neutrophils (neutrophilia), whereas parasitic and allergic responses induce eosinophilia. Viral infections tend to produce a decrease in neutrophils (neutropenia) and an increase in lymphocytes (lymphocytosis). A decrease in white blood cells (leukopenia) may occur with overwhelming infections or an impaired ability to produce white blood cells.

**Lymphadenitis**

Localized acute and chronic inflammation may lead to a reaction in the lymph nodes that drain the affected area. This response represents a nonspecific response to mediators released from the injured tissue or an immunologic response to
a specific antigen. Painful palpable nodes are more commonly associated with inflammatory processes, whereas nonpainful lymph nodes are more characteristic of neoplasms.

**IN SUMMARY**

Inflammation describes a local response to tissue injury and can present as an acute or chronic condition. The classic signs of an acute inflammatory response are redness, swelling, local heat, pain, and loss of function. Acute inflammation is orchestrated by the endothelial cells that line blood vessels, phagocytic leukocytes (mainly neutrophils and monocytes) that circulate in the blood, and tissue cells (macrophages, mast cells) that direct the tissues responses. Acute inflammation involves a hemodynamic phase during which blood flow and capillary permeability are increased and a cellular phase during which phagocytic white blood cells move into the area to engulf and degrade the inciting agent. The inflammatory response is orchestrated by chemical mediators such as cytokines and chemokines, histamine, prostaglandins, PAF, complement fragments, and reactive molecules liberated by leukocytes. Acute inflammation may involve the production of exudates containing serous fluid (serous exudate), red blood cells (hemorrhagic exudate), fibrinogen (fibrinous exudate), or tissue debris and white blood cell breakdown products (purulent exudate).

In contrast to acute inflammation, which is self-limiting, chronic inflammation is prolonged and usually is caused by persistent irritants, most of which are insoluble and resistant to phagocytosis and other inflammatory mechanisms. Chronic inflammation involves the presence of mononuclear cells (lymphocytes and macrophages) rather than granulocytes. The systemic manifestations of inflammation include the systemic effects of the acute-phase response, such as fever and lethargy; increased ESR and levels of high-sensitivity CRP and other acute-phase proteins; leukocytosis or, in some cases, leukopenia; and enlargement of the lymph nodes that drain the affected area.

**Tissue Repair**

Tissue repair, which overlaps the inflammatory process, is a response to tissue injury and represents an attempt to maintain normal body structure and function. It can take the form of regeneration in which the injured cells are replaced with cells of the same type, sometimes leaving no residual trace of previous injury, or it can take the form of replacement by connective tissue, which leaves a permanent scar. Both regeneration and repair by connective tissue replacement are determined by similar mechanisms involving cell migration, proliferation, and differentiation, as well as interaction with the ECM.

**Tissue Regeneration**

Body organs and tissues are composed of two types of structures: parenchymal and stromal. The parenchymal tissues contain the functioning cells of an organ or body part (e.g., hepatocytes, renal tubular cells). The stromal tissues consist of the supporting connective tissues, blood vessels, ECM, and nerve fibers.

Tissue regeneration involves replacement of the injured tissue with cells of the same type, leaving little or no evidence of the previous injury. The capacity for regeneration varies with the tissue and cell type. Body cells are divided into three types according to their ability to undergo regeneration: labile, stable, or permanent cells. Labile cells are those that continue to divide and replicate throughout life, replacing cells that are continually being destroyed. They include the surface epithelial cells of the skin, oral cavity, vagina, and cervix; the columnar epithelium of the gastrointestinal tract, uterus, and fallopian tubes; the transitional epithelium of the urinary tract; and bone marrow cells. Stable cells are those that normally stop dividing when growth ceases. However, these cells are capable of undergoing regeneration when confronted with an appropriate stimulus and are thus capable of reconstituting the tissue of origin. This category includes the parenchymal cells of the liver and kidney, smooth muscle cells, and vascular endothelial cells. Permanent or fixed cells cannot undergo mitotic division. The fixed cells include nerve cells, skeletal muscle cells, and cardiac muscle cells. These cells do not normally regenerate; once destroyed, they are replaced with fibrous scar tissue that lacks the functional characteristics of the destroyed tissue.

**Fibrous Tissue Repair**

Severe or persistent injury with damage to both the parenchymal cells and ECM leads to a situation in which the repair cannot be accomplished with regeneration alone. Under these conditions, repair occurs by replacement with connective tissue, a process that involves generation of granulation tissue and formation of scar tissue.

Granulation tissue is a glistening red, moist connective tissue that contains newly formed capillaries, proliferating fibroblasts, and residual inflammatory cells. The development of granulation tissue involves the growth of new capillaries (angiogenesis), fibrogenesis, and involution to the formation of scar tissue. Angiogenesis involves the generation and
sprouting of new blood vessels from preexisting vessels. These sprouting capillaries tend to protrude from the surface of the wound as minute red granules, imparting the name granulation tissue. Eventually, portions of the new capillary bed differentiate into arterioles and venules. Fibrogenesis involves the influx of activated fibroblasts. Activated fibroblasts secrete ECM components, including fibronectin, hyaluronic acid, proteoglycans, and collagen. Fibronectin and hyaluronic acid are the first to be deposited in the healing wound, and proteoglycans appear later. Because the proteoglycans are hydrophilic, their accumulation contributes to the edematous appearance of the wound. The initiation of collagen synthesis contributes to the subsequent formation of scar tissue. Scar formation builds on the granulation tissue framework of new vessels and loose ECM. The process occurs in two phases: (1) emigration and proliferation of fibroblasts into the site of injury and (2) deposition of ECM by these cells. As healing progresses, the number of proliferating fibroblasts and new vessels decreases, and there is increased synthesis and deposition of collagen. Collagen synthesis is important to the development of strength in the healing wound site. Ultimately, the granulation tissue scaffolding evolves into a scar composed of largely inactive spindle-shaped fibroblasts, dense collagen fibers, fragments of elastic tissue, and other ECM components. As the scar matures, vascular degeneration eventually transforms the highly vascular granulation tissue into a pale, largely avascular scar.

**Regulation of the Healing Process**

Tissue healing is regulated by the actions of chemical mediators and growth factors that orchestrate the healing process as well as orchestrate the interactions between the extracellular and cell matrix.32–36

**Chemical Mediators and Growth Factors.** Considerable research has contributed to the understanding of chemical mediators and growth factors that orchestrate the healing process.1 These chemical mediators and growth factors are released in an orderly manner from many of the cells that participate in tissue regeneration and the healing process. The chemical mediators include the interleukins, interferons, TNF-α, and arachidonic acid derivatives (prostaglandins and leukotrienes) that participate in the inflammatory response.1,11 The growth factors are hormone-like molecules that interact with specific cell surface receptors to control processes involved in tissue repair and wound healing.32–36 They may act on adjacent cells or on the cell producing the growth factor. The growth factors are named for their tissue of origin (e.g., platelet-derived growth factor [PDGF], fibroblast growth factor [FGF]), their biologic activity (e.g., transforming growth factor [TGF]), or the cells on which they act (e.g., epithelial growth factor [EGF] or connective tissue growth factor beta [TGF-B] or VEGF).33 The growth factors control the proliferation, differentiation, and metabolism of cells during wound healing. For example, the VEGF stimulates wound healing by way of collagen deposition, angiogenesis, and epithelialization.34 The vitronectin growth factor complex has demonstrated specifically good healing with venous ulcers, decubitus ulcers, and diabetic foot ulcers.35 The growth factors assist in regulating the inflammatory process; serve as chemoattractants for neutrophils, monocytes (macrophages), fibroblasts, and epithelial cells; stimulate angiogenesis; and contribute to the generation of the ECM.

**Extracellular Matrix.** The understanding of tissue regeneration and repair has expanded over the past several decades to encompass the complex environment of the ECM. The ECM is secreted locally and assembles into a network of spaces surrounding tissue cells. There are three basic components of the ECM: fibrous structural proteins (e.g., collagen and elastin fibers), water-hydrated gels (e.g., proteoglycans and hyaluronic acid) that permit resilience and lubrication, and adhesive glycoproteins (e.g., fibronectin and laminin) that connect the matrix elements to each other and to cells. The ECM occurs in two basic forms: (1) the basement membrane that surrounds epithelial, endothelial, and smooth muscle cells and (2) the interstitial matrix, which is present in the spaces between cells in connective tissue and between the epithelium and supporting cells of blood vessels.

The ECM provides turgor to soft tissue and rigidity to bone; it supplies the substratum for cell adhesion; it is involved in the regulation of growth, movement, and differentiation of the cells surrounding it; and it provides for the storage and presentation of regulatory molecules that control the repair process. The ECM also provides the scaffolding for tissue renewal. Although the cells in many tissues are capable of regeneration, injury does not always result in restoration of normal structure unless the ECM is intact. The integrity of the underlying basement membrane, in particular, is critical to the regeneration of tissue. When the basement membrane is disrupted, cells proliferate in a haphazard way, resulting in disorganized and nonfunctional tissues.

Critical to the process of wound healing is the transition from granulation tissue to scar tissue, which involves shifts in the composition of the ECM. In the transitional process, the ECM components are degraded by proteases (enzymes) that are secreted locally by a variety of cells (fibroblasts, macrophages, neutrophils, synovial cells, and epithelial cells). Some of the proteases, such as the collagenases, are highly specific, cleaving particular proteins at a small number of sites.36 This allows for the structural integrity of the ECM to be retained while cell migration occurs. Because of their potential to produce havoc in tissues, the actions of the proteases are tightly controlled. They are typically elaborated in an inactive form that must be activated by chemical mediators that are present at the site of injury, and they are rapidly inactivated by tissue inhibitors. Research has focused on the unregulated action of the proteases in disorders such as cartilage matrix breakdown in arthritis and neuroinflammation in multiple sclerosis, and arterial stiffness causing increased peripheral resistance.36,37 Evidence from an animal study supports a lack of tissue inhibitor of metalloproteinase 2 can lead to left ventricular heart dysfunction and poor EMC remodeling in response to biomechanical stress.38
Wound healing involves the restoration of the integrity of injured tissue. The healing of skin wounds, which are commonly used to illustrate the general principles of wound healing, is generally divided into three phases: (1) the inflammatory phase, (2) the proliferative phase, and (3) the wound contraction and remodeling phase. Each of these phases is mediated through cytokines and growth factors.

**Inflammatory Phase**

The inflammatory phase begins at the time of injury with the formation of a blood clot and the migration of phagocytic white blood cells into the wound site. The first cells to arrive, the neutrophils, ingest and remove bacteria and cellular debris. After 24 hours, the neutrophils are joined by macrophages, which continue to ingest cellular debris and play an essential role in the production of growth factors for the proliferative phase.

**Proliferative Phase**

The primary processes during this phase focus on the building of new tissue to fill the wound space. The key cell during this phase is the fibroblast, a connective tissue cell that synthesizes and secretes the collagen, proteoglycans, and glycoproteins needed for wound healing. Fibroblasts also produce a family of growth factors that induce angiogenesis (growth of new blood vessels) and endothelial cell proliferation and migration. The final component of the proliferative phase is epithelialization, during which epithelial cells at the wound edges proliferate to form a new surface layer that is similar to that which was destroyed by the injury.
Wound Healing

Injured tissues are repaired by regeneration of parenchymal cells or by connective tissue repair in which scar tissue is substituted for the parenchymal cells of the injured tissue. The primary objective of the healing process is to fill the gap created by tissue destruction and to restore the structural continuity of the injured part. When regeneration cannot occur, healing by replacement with a connective tissue scar provides the means for maintaining this continuity. Although scar tissue fills the gap created by tissue death, it does not repair the structure with functioning parenchymal cells. Because the regenerative capabilities of most tissues are limited, wound healing usually involves some connective tissue repair. The following discussion particularly addresses skin wounds.

Wound Healing by Primary and Secondary Intention

Depending on the extent of tissue loss, wound closure and healing occur by primary or secondary intention (Fig. 14.8). A sutured surgical incision is an example of healing by primary intention. Larger wounds (e.g., burns and large surface wounds) that have a greater loss of tissue and contamination heal by secondary intention. Healing by secondary intention is slower than healing by primary intention and results in the formation of larger amounts of scar tissue. A wound that might otherwise have healed by primary intention may become infected and heal by secondary intention.

Phases of Wound Healing

Wound healing is commonly divided into three phases: (1) the inflammatory phase, (2) the proliferative phase, and (3) the maturation or remodeling phase. The duration of the phases is fairly predictable in wounds healing by primary intention. In

FIGURE 14.8 • Healing of a skin wound by primary and secondary intention.
In the absence of macrophages.

**Inflammatory Phase.** The inflammatory phase of wound healing begins at the time of injury and is a critical period because it prepares the wound environment for healing. It includes hemostasis and the vascular and cellular phases of inflammation. Hemostatic processes are activated immediately at the time of injury. There is constriction of injured blood vessels and initiation of blood clotting through platelet activation and aggregation. After a brief period of constriction, the same vessels dilate and capillaries increase their permeability, allowing plasma and blood components to leak into the injured area. In small surface wounds, the clot loses fluid and becomes a hard, desiccated scab that protects the area.

The cellular phase of inflammation follows and is evidenced by the migration of phagocytic white blood cells that digest and remove invading organisms, fibrin, extracellular debris, and other foreign matter. The neutrophils are the first cells to arrive and are usually gone by day 3 or 4. They ingest bacteria and cellular debris. After approximately 24 hours, macrophages, which are larger phagocytic cells, enter the wound area and remain for an extended period. These cells, arising from blood monocytes, are essential to the healing process. Their functions include phagocytosis and release of growth factors that stimulate epithelial cell growth and angiogenesis and attract fibroblasts. When a large defect occurs in deeper tissues, neutrophils and macrophages are required to remove the debris and facilitate wound closure. Although a wound may heal in the absence of neutrophils, it cannot heal in the absence of macrophages.

**Proliferative Phase.** The proliferative phase of healing usually begins within 2 to 3 days of injury and may last as long as 3 weeks in wounds healing by primary intention. The primary processes during this time focus on the building of new tissue to fill the wound space. The key cell during this phase is the fibroblast. The fibroblast is a connective tissue cell that synthesizes and secretes collagen and other intercellular elements needed for wound healing. Fibroblasts also produce a family of growth factors that induce angiogenesis and endothelial cell proliferation and migration.

As early as 24 to 48 hours after injury, fibroblasts and vascular endothelial cells begin proliferating to form the granulation tissue that serves as the foundation for scar tissue development. This tissue is fragile and bleeds easily because of the numerous, newly developed capillary buds. Wounds that heal by secondary intention have more necrotic debris and exudate that must be removed, and they involve larger amounts of granulation tissue. The newly formed blood vessels are semipermeable and allow plasma proteins and white blood cells to leak into the tissues.

The final component of the proliferative phase is epithelialization, which is the migration, proliferation, and differentiation of the epithelial cells at the wound edges to form a new surface layer that is similar to the one destroyed by the injury. In wounds that heal by primary intention, these epidermal cells proliferate and seal the wound within 24 to 48 hours.28 Because epithelial cell migration requires a moist vascular wound surface and is impeded by a dry or necrotic wound surface, epithelialization is delayed in open wounds until a bed of granulation tissue has formed. When a scab has formed on the wound, the epithelial cells migrate between it and the underlying viable tissue; when a significant portion of the wound has been covered with epithelial tissue, the scab lifts off.

At times, excessive granulation tissue, sometimes referred to as proud flesh, may form and extend above the edges of the wound, preventing reepithelialization from taking place. Surgical removal or chemical cauterization of the defect allows healing to proceed.

As the proliferative phase progresses, there is continued accumulation of collagen and proliferation of fibroblasts. Collagen synthesis reaches a peak within 5 to 7 days and continues for several weeks, depending on wound size. By the second week, the white blood cells have largely left the area, the edema has diminished, and the wound begins to blanch as the small blood vessels become thrombosed and degenerate.

**Remodeling Phase.** The third phase of wound healing, the remodeling process, begins approximately 3 weeks after injury and can continue for 6 months or longer, depending on the extent of the wound. As the term implies, there is continued remodeling of scar tissue by simultaneous synthesis of collagen by fibroblasts and lysis by collagenase enzymes. As a result of these two processes, the architecture of the scar becomes reoriented to increase the tensile strength of the wound.

Most wounds do not regain the full tensile strength of unwounded skin after healing is completed. Carefully sutured wounds immediately after surgery have approximately 70% of the strength of unwounded skin, largely because of the placement of the sutures. This allows people to move about freely after surgery without fear of wound separation. When the sutures are removed, usually at the end of the first week, wound strength is approximately 10%. It increases rapidly over the next 4 weeks and then slows, reaching a plateau of approximately 70% to 80% of the tensile strength of unwounded skin at the end of 3 months.28

An injury that heals by secondary intention undergoes wound contraction during the proliferative and remodeling phases. As a result, the scar that forms is considerably smaller than the original wound. Cosmetically, this may be desirable because it reduces the size of the visible defect. However, contraction of scar tissue over joints and other body structures tends to limit movement and cause deformities. As a result of loss of elasticity, scar tissue that is stretched fails to return to its original length.

An abnormality in healing by scar tissue repair is keloid formation. Keloids are tumor-like masses caused by excess production of scar tissue (Fig. 14.9). The tendency toward development of keloids is more common in African Americans and seems to have a genetic basis.
Factors That Affect Wound Healing

Many local and systemic factors influence wound healing. Among the causes of impaired wound healing are malnutrition; impaired blood flow and oxygen delivery; impaired inflammatory and immune responses; infection, wound separation, and foreign bodies; and age effects. Specific disorders in inflammatory and immune responses; infection, wound separation; impaired blood flow and oxygen delivery; impaired lagen production, and angiogenesis. Wounds in ischemic tissues must have adequate blood flow to supply the necessary nutrients and to remove the resulting waste, local toxins, bacteria, and other debris. Impaired wound healing due to poor blood flow may occur as a result of wound conditions (e.g., swelling) or preexisting health problems. Arterial disease and venous pathology are well-documented causes of impaired wound healing. In situations of trauma, a decrease in blood volume may cause a reduction in blood flow to injured tissues.

Molecular oxygen is required for collagen synthesis. Hypoxia is a serious factor in preventing wound healing since it has been shown to decrease fibroblast growth, collagen production, and angiogenesis. Wounds in ischemic tissue become infected more frequently than wounds in well-vascularized tissue. PMNs and macrophages require oxygen for destruction of microorganisms that have invaded the area. Although these cells can accomplish phagocytosis in a relatively anoxic environment, they cannot digest bacteria.

Hyperbaric oxygen is a treatment that has demonstrated improved wound healing in multiple types of injuries. This therapy delivers 96% to 100% oxygen at greater than twice the synthesis of new cells.

Although most vitamins are essential cofactors for the daily functions of the body, vitamins A and C play an essential role in the healing process. Vitamin C is needed for collagen synthesis. In vitamin C deficiency, improper sequencing of amino acids occurs, proper linking of amino acids does not take place, the by-products of collagen synthesis are not removed from the cell, new wounds do not heal properly, and old wounds may fall apart. Administration of vitamin C rapidly restores the healing process to normal. Vitamin A functions in stimulating and supporting epithelialization, capillary formation, and collagen synthesis. Vitamin A also has been shown to counteract the anti-inflammatory effects of corticosteroid drugs and can be used to reverse these effects in people who are on chronic steroid therapy. The B vitamins are important cofactors in enzymatic reactions that contribute to the wound-healing process. All are water soluble and, with the exception of vitamin B_{12}, which is stored in the liver, almost all must be replaced daily. Vitamin K plays an indirect role in wound healing by preventing bleeding disorders that contribute to hematoma formation and subsequent infection.

The role of minerals in wound healing is less clearly defined. The macrominerals, including sodium, potassium, calcium, and phosphorus, as well as the microminerals, such as copper and zinc, must be present for normal cell function. Zinc is a cofactor in a variety of enzyme systems responsible for cell proliferation. In animal studies, zinc has been found to aid in reepithelialization.

Blood Flow and Oxygen Delivery. For healing to occur, wounds must have adequate blood flow to supply the necessary nutrients and to remove the resulting waste, local toxins, bacteria, and other debris. Impaired wound healing due to poor blood flow may occur as a result of wound conditions (e.g., swelling) or preexisting health problems. Arterial disease and venous pathology are well-documented causes of impaired wound healing. In situations of trauma, a decrease in blood volume may cause a reduction in blood flow to injured tissues.

Molecular oxygen is required for collagen synthesis. Hypoxia is a serious factor in preventing wound healing since it has been shown to decrease fibroblast growth, collagen production, and angiogenesis. Wounds in ischemic tissue become infected more frequently than wounds in well-vascularized tissue. PMNs and macrophages require oxygen for destruction of microorganisms that have invaded the area. Although these cells can accomplish phagocytosis in a relatively anoxic environment, they cannot digest bacteria.

**Image Description:**

**Figure 14.9** - Keloid. A light-skinned black woman with keloid that developed after ear piercing. (From Rubin R., Strayer D. E. (Eds.) (2012). Rubin’s pathology: Clinicopathologic foundations of medicine (6th ed., p. 97), Philadelphia, PA: Lippincott Williams & Wilkins.)
the normal atmospheric pressure at sea level.\textsuperscript{43} The goal is to increase oxygen delivery to tissues by increasing the partial pressure of oxygen dissolved in the plasma. An increase in tissue oxygen tension by hyperbaric oxygen enhances wound healing by a number of mechanisms, including the increased killing of bacteria by neutrophils, impaired growth of anaerobic bacteria, and the promotion of angiogenesis and fibroblast activity. Hyperbaric oxygen is generally reserved for the treatment of problem wounds in which hypoxia and infection interfere with healing.

**Impaired Inflammatory and Immune Responses.** Inflammatory and immune mechanisms function in wound healing. Inflammation is essential to the first phase of wound healing, and immune mechanisms prevent infections that impair wound healing. Among the conditions that impair inflammation and immune function are disorders of phagocytic function, diabetes mellitus, and therapeutic administration of corticosteroid drugs.

Phagocytic disorders may be divided into extrinsic and intrinsic defects. Extrinsic disorders are those that reduce the total number of phagocytic cells (e.g., immunosuppressive agents), impair the attraction of phagocytic cells to the wound site, interfere with the engulfment of bacteria and foreign agents by the phagocytic cells (i.e., opsonization), or suppress the total number of phagocytic cells (e.g., immunosuppressive agents). Intrinsic phagocytic disorders are the result of enzymatic deficiencies in the metabolic pathway for destroying the ingested bacteria by the phagocytic cell. The intrinsic phagocytic disorders include chronic granulomatous disease, an X-linked inherited disease in which there is a deficiency of the myeloperoxidase or NADPH oxidase enzymes. Deficiencies of these compounds prevent generation of superoxide and hydrogen peroxide needed for killing bacteria.

Many people with diabetes mellitus who have wounds do not respond well to traditional methods of wound treatment because of their high blood glucose levels.\textsuperscript{44} Evidence shows delayed wound healing and complications such as prolonged infections in people with diabetes.\textsuperscript{44} Of particular importance is the effect of hyperglycemia on phagocytic function. Neutrophils, for example, have diminished chemotactic and phagocytic function, including engulfment and intracellular killing of bacteria, when exposed to altered glucose levels. Small blood vessel disease is also common among people with diabetes, impairing the delivery of inflammatory cells, oxygen, and nutrients to the wound site.

The therapeutic administration of corticosteroid drugs decreases the inflammatory process and may delay the healing process. These hormones decrease capillary permeability during the early stages of inflammation, impair the phagocytic property of the leukocytes, and inhibit fibroblast proliferation and function.

**Infection, Wound Separation, and Foreign Bodies.** Wound contamination, wound separation, and foreign bodies delay wound healing. Infection impairs all dimensions of wound healing.\textsuperscript{45} It prolongs the inflammatory phase, impairs the formation of granulation tissue, and inhibits proliferation of fibroblasts and deposition of collagen fibers. All wounds are contaminated at the time of injury. Although body defenses can handle the invasion of microorganisms at the time of wounding, badly contaminated wounds can overwhelm host defenses. Trauma and existing impairment of host defenses also can contribute to the development of wound infections.

Approximation of the wound edges (i.e., suturing of an incision type of wound) greatly enhances healing and prevents infection. Epithelialization of a wound with closely approximated edges occurs within 1 to 2 days. Large, gaping wounds tend to heal more slowly because it is often impossible to effect wound closure with this type of wound. Mechanical factors such as increased local pressure or torsion can cause wounds to pull apart, or dehisce. Foreign bodies tend to invite bacterial contamination and delay healing. Fragments of wood, steel, glass, and other compounds may have entered the wound at the site of injury and can be difficult to locate when the wound is treated. Sutures are also foreign bodies, and although needed for the closure of surgical wounds, they are an impediment to healing. This is why sutures are removed as soon as possible after surgery. Wound infections are of special concern in people with implantation of foreign bodies such as orthopedic devices (e.g., pins, stabilization devices), cardiac pacemakers, and shunt catheters. These infections are difficult to treat and may require removal of the device. New topical therapeutics regarding debridement and diagnostic methods have been successful in breaking down the microbial biofilm that develops on wound surfaces.\textsuperscript{46,47}

**Bite Wounds.** Animal and human bites are particularly troublesome in terms of infection.\textsuperscript{48–52} The animal inflicting the bite, the location of the bite, and the type of injury are all important determinants of whether the wound becomes infected. Cat bites (30% to 50%) are more apt to become infected with *Pasteurella multocida* compared to human bites.\textsuperscript{50} Dog bites, for unclear reasons, become infected only approximately 5% of the time and generally either with *P. multocida* or *Capnocytophaga canimorsus*.\textsuperscript{50} Bites inflicted by children are usually superficial and seldom become infected, whereas bites inflicted by adults have a much higher rate of infection. Puncture wounds are more likely to become infected than lacerations, probably because lacerations are easier to irrigate and debride.

Treatment of bite wounds involves vigorous irrigation and cleansing as well as debridement or removal of necrotic tissue. Whether bite wounds are closed with sutures to promote healing by primary intention depends on the location of the bite and whether the wound is already infected. Wounds that are not infected and require closure for mechanical or cosmetic reasons may be sutured. Wounds of the hand are not usually sutured because closed-space infection of the hand can produce loss of function. Antibiotics are usually administered prophylactically to people with high-risk bites (e.g., cat bites in any location and human or animal bites to the hand). All people with bites should be evaluated to determine if tetanus or rabies prophylaxis is needed.
The Effect of Age on Wound Healing

Wound Healing in Neonates and Children. Wound healing in children is similar to that in the adult population. The child has a greater capacity for repair than the adult but may lack the reserves needed to ensure proper healing. A lack in reserves is evidenced by an easily upset electrolyte balance, a sudden change in temperature, and rapid spread of infection. The neonate and small child may have an immature immune system with no antigenic experience with organisms that contaminate wounds. The younger the child, the more likely the immune system is not fully developed.

Successful wound healing also depends on adequate nutrition. Children need sufficient calories to maintain growth and wound healing. The premature infant is often born with immature organ systems and minimal energy stores but high metabolic requirements—a condition that predisposes to impaired wound healing.

Children with certain comorbidities such as diabetes and malabsorption problems will be at higher risk for wound complication. Likewise these children will be more apt to develop a skin breakdown or pressure sore. The Braden Q Scale is used to assess children’s skin breakdown and is designed specifically for use with children.

Wound Healing in Older Adults. A number of structural and functional changes occur in aging skin, including a decrease in dermal thickness, a decline in collagen content, and a loss of elasticity. The observed changes in skin that occur with aging are complicated by the effects of sun exposure. Since the effects of sun exposure are cumulative, older adults show more changes in skin structure.

Wound healing is thought to be progressively impaired with aging. Older adults have reduced collagen and fibroblast synthesis, impaired wound contraction, and slower reepithelialization of open wounds. Although wound healing may be delayed, most wounds heal, even in the debilitated older adult undergoing major surgical procedures.

Older adults are more vulnerable to chronic wounds, especially pressure, diabetic, and ischemic ulcers, compared to younger people, and these wounds heal more slowly. However, these wounds are more likely due to other disorders such as immobility, diabetes mellitus, or vascular disease, rather than aging. New disease-specific formulas for older adults with slow healing wounds are being studied, and pharmacoeconomic evaluations are being considered. Evidence suggests older adults should have their nutritional formula assessed to make sure it correlates with each older adult’s needs and that it specifically includes arginine, zinc, protein, and vitamin C.

IN SUMMARY

The ability of tissues to repair damage due to injury depends on the body’s ability to replace the parenchymal cells and to organize them as they were originally. Regeneration describes the process by which tissue is replaced with cells of a similar type and function. Healing by regeneration is limited to tissue with cells that are able to divide and replace the injured cells. Body cells are divided into types according to their ability to regenerate: labile cells, such as the epithelial cells of the skin and gastrointestinal tract, which continue to regenerate throughout life; stable cells, such as those in the liver, which normally do not divide but are capable of regeneration when confronted with an appropriate stimulus; and permanent or fixed cells, such as nerve cells, which are unable to regenerate. Scar tissue repair involves the substitution of fibrous connective tissue for injured tissue that cannot be repaired by regeneration.

Wound healing occurs by primary and secondary intention and is commonly divided into three phases: the inflammatory phase, the proliferative phase, and the maturational or remodeling phase. In wounds healing by primary intention, the duration of the phases is fairly predictable. In wounds healing by secondary intention, the process depends on the extent of injury and the healing environment. Wound healing can be impaired or complicated by factors such as malnutrition; restricted blood flow and oxygen delivery; diminished inflammatory and immune responses; and infection, wound separation, and the presence of foreign bodies. With infants and young children wound healing is generally not impaired unless there is a hygiene issue and adolescents tend to have dry skin that can decrease the rate of wound healing. Older adults experience dry skin and decreased subcutaneous fat that can lead to increased time with wound healing.

REVIEW EXERCISES

1. A 15-year-old boy presents with abdominal pain, a temperature of 38°C (100.5°F), and an elevated white blood cell count of 13,000/µL, with an increase in neutrophils. A tentative diagnosis of appendicitis is made.
   A. Explain the significance of pain as it relates to the inflammatory response.
   B. What is the cause of the fever and elevated white blood cell count?
   C. What would be the preferred treatment for this boy?

2. Aspirin and other NSAIDs are used to control the manifestations of chronic inflammatory disorders such as arthritis.
   A. Explain their mechanism of action in terms of controlling the inflammatory response.

3. After a myocardial infarction, the area of heart muscle that has undergone necrosis because of a lack of blood supply undergoes healing by replacement with scar tissue.
   A. Compare the functioning of the heart muscle that has been replaced by scar tissue with that of the normal surrounding heart muscle.
4. A 35-year-old man presents with a large abscess on his leg. He tells you he injured his leg while doing repair work on his house and he thinks there might be a wood sliver in the infected area.

A. Explain the events that participate in formation of an abscess.
B. He is told that incision and drainage of the lesion will be needed so healing can take place. Explain.
C. He is reluctant to have the procedure done and asks whether an antibiotic would work as well. Explain why antibiotics alone are usually not effective in eliminating the microorganisms contained in an abscess.

Disorders of the Immune Response

Nancy A. Moriber

The human immune system is a complex, multidimensional system designed to protect the host against invasion by foreign substances, microorganisms, and toxins. In addition, it helps to protect against the proliferation of neoplastic cells and plays a key role in the process of inflammation and wound healing. Unfortunately, under certain circumstances the immune system can become inefficient or hyperactive, causing the development of debilitating and/or life-threatening diseases. These disease processes can take the form of immunodeficiency disorders, allergic or hypersensitivity reactions, transplant rejection, and autoimmune disorders. Regardless of the manifestation, the underlying cause can be traced back to an abnormality in one of the cellular or chemical components of the innate and adaptive immune responses.

IMMUNODEFICIENCY DISORDERS

Humoral (B Cell) Immunodeficiencies
  - Transient Hypogammaglobulinemia of Infancy
  - Primary Humoral Immunodeficiency Disorders
  - Secondary Humoral Immunodeficiency Disorders
Cell-Mediated (T Cell) Immunodeficiencies
  - Primary Cell-Mediated Immunodeficiency Disorders
  - Secondary Cell-Mediated Immunodeficiency Disorders
Combined T-Cell and B-Cell Immunodeficiencies
  - Severe Combined Immunodeficiency Disorders
  - Combined Immunodeficiency Disorders
Disorders of the Complement System
  - Primary Disorders of the Complement System
  - Secondary Disorders of the Complement System
Disorders of Phagocytosis
  - Primary Disorders of Phagocytosis
  - Secondary Disorders of Phagocytosis
Stem Cell Transplantation

HYPERSENSITIVITY DISORDERS

Type I, Immediate Hypersensitivity Disorders
  - Anaphylactic (Systemic) Reactions
  - Atopic (Local) Reactions
Type II, Antibody-Mediated Disorders
  - Complement-Activated Cell Destruction
  - Antibody-Dependent Cell Cytotoxicity
  - Complement- and Antibody-Mediated Inflammation
  - Antibody-Mediated Cellular Dysfunction
Type III, Immune Complex–Mediated Disorders
  - Systemic Immune Complex Disorders
  - Localized Immune Complex Reactions
Type IV, Cell-Mediated Hypersensitivity Disorders
  - Allergic Contact Dermatitis
  - Hypersensitivity Pneumonitis
  - Latex Allergy

TRANSPLANTATION IMMUNOPATHOLOGY

Mechanisms Involved in Transplant Rejection
  - Graft-Versus-Host Disease

AUTOIMMUNE DISEASE

Immunologic Tolerance
  - B-Cell Tolerance
  - T-Cell Tolerance
Mechanisms of Autoimmune Disease
  - Heredity
  - Environmental Factors
Diagnosis and Treatment of Autoimmune Disease

Immune deficiency is defined as an abnormality in one or more parts of the immune system that results in an increased susceptibility to disease states normally eradicated by a properly functioning immune response including infection by invading microorganisms or the development of neoplastic syndromes. Immunodeficiency syndromes can be classified as primary or secondary (acquired later in life). Primary immunodeficiency disorders are either congenital or inherited as sex-linked,
autosomal dominant, or autosomal recessive traits. Secondary immunodeficiency disorders develop later in life as a result of other pathophysiologic states such as malnutrition; disseminated cancers; infection of the cells of the immune system, most notably with human immunodeficiency virus (HIV); and treatment with immunosuppressive drugs, such as chemotherapeutic agents, corticosteroids, or transplant rejection medications. The clinical manifestations and the impact on the client’s day-to-day function are dependent upon the specific immunodeficiency disorder and the degree of immune system dysfunction. The various categories of immunodeficiency disorders are summarized in Chart 15.1.

The immune system is made up of two distinct but interrelated systems: the innate and adaptive immune systems. These two systems work in concert to protect the body from infection and disease. The innate immune system is the body’s first line of defense against infection. It employs rapid yet nonspecific cellular and chemical responses. These include phagocytic leukocytes (i.e., neutrophils, macrophages); natural killer (NK) cells; chemical mediators, such as chemokines and cytokines; and the complement system. The adaptive immune system differs from the innate immune system in its ability to exhibit “memory” for invading organisms and toxic substances. The adaptive immune response develops more slowly but with a great deal of specificity. The T and B lymphocytes of the innate immune system possess the ability to express their receptors (T cells) and produce immunoglobulins (Igs) (B cells) in billions of different combinations, which enables them to target billions of different epitopes, viruses, and microorganisms.

The ability of the adaptive immune system to function effectively is dependent upon the interaction of two distinct but intimately connected mechanisms, the humoral (B cell–mediated) and cell-mediated (T cell–mediated) responses. The humoral immune response relies upon the ability of B lymphocytes to produce antigen-specific Igs and “memory” cells. In contrast, the cell-mediated response relies upon the ability of the T lymphocytes to produce various cytokines, to present antigen to B lymphocytes for destruction, and, in the case of cytotoxic T cells, to kill cells infected with intracellular organisms. It is essential that the cells of the humoral and cell-mediated responses work together in defense against invading microorganism and disease processes. For example, B-lymphocyte activation and subsequent Ig production (i.e., IgG versus IgA) are dependent upon the presence of certain cytokines, which are specifically produced by helper T cells. Conversely, cytotoxic T lymphocytes depend on the presence of specific Igs produced by B cells (plasma cells) in order to destroy virally infected cells and cell-free viral particles before they spread to other cellular targets.

Although primary immune deficiencies (PIDs) are rare as individual disease processes, they are relatively common as a general group of disorders. Recent estimates put the overall prevalence of PIDs in the United States at 1:2000. Approximately 65% of these cases present as a primary
antibody deficiency syndrome. The incidence has risen from 2.4 per 100,000 for the years 1976 to 1980 to 10.3 per 100,000 from 2001 to 2006. This increase has been attributed to an increased awareness and, therefore, diagnoses of PIDs, not to an increase in the number of actual new cases. In recent years there has been an abundance of research conducted in order to identify the genetic and biochemical defects that cause the development of the PIDs. This has led to the development of improved treatments and therapies for patients with PIDs decreasing the incidence of life-threatening infections. Currently, there are over 100 documented PIDs, and new disorders are continuously being identified. Most of these disorders are inherited as autosomal recessive traits, several are sex linked and caused by mutations in the X chromosome, and the causes of some have yet to be identified. The root cause of many of the PIDs involves mutations that affect the signaling pathways (e.g., cytokines and cytokine signaling, receptor subunits, and metabolic pathways) that dictate immune cell development and function. Autoimmunity is frequently associated with the PIDs because the ability of the immune system to differentiate self from nonself is also affected.

Many primary immunodeficiency disorders have severely debilitating and life-threatening consequences. Although early detection is possible, pediatricians do not normally conduct regular screening. For infants born with severe combined T- and B-cell immunodeficiency, early diagnosis is essential before the development of severe infections and the administration of live attenuated virus vaccines (e.g., measles, mumps, rubella, varicella, bacillus Calmette-Guérin), which could have devastating and life-threatening consequences.

Children with PID often present with a history of recurrent, severe infections that are resistant to treatment. In fact, the average age of referral for immune testing after recurrent severe infection is about 6 months of age. The infections frequently involve the respiratory tract and are the result of organisms not traditionally seen in this population. The Jeffrey Modell Foundation/Primary Immunodeficiency Resource Center has developed a list of the 10 most common warning signs that a child may suffer from a PID. These include recurrent bouts of ear infections, sinus infections, recurrent skin or organ abscesses, and a positive family history of primary immunodeficiency. Because these disorders are frequently inherited, a positive family history may help in the diagnosis. Areas of the world with high consanguinity (descended from the same ancestor) rates have been shown to have a much higher prevalence rate than that in the general population.

In one cohort of patients at the Children’s Hospital in Cairo, Egypt, 62.5% of the patients diagnosed with PIDs were the offspring of consanguineous parents. In addition, identification of the infectious organism can help in the diagnosis of the specific form of PID. Bacterial infections (Streptococcus pneumoniae and Haemophilus influenzae) are frequently seen cases of antibody deficiency, whereas severe viral, fungal, and opportunistic infections most often characterize T-cell deficiencies. Recurrent infections with encapsulated bacteria, particularly S. pneumoniae, characterize people with complement deficiencies. Recurrent infections with staphylococcal and other catalase-positive organisms are common in people with disorders primarily affecting phagocytosis. Table 15.1 summarizes types of infections that occur with the different types of primary immunodeficiency disorders.

Humoral (B Cell) Immunodeficiencies

Humoral immunodeficiencies are primarily associated with B-cell dysfunction and decreased Ig production. Because the B lymphocytes are essential for normal defense against bacterial invasion, people with humoral immunodeficiencies are at increased risk for recurrent infections by *S. pneumoniae*, *H. influenzae*, *Staphylococcus aureus*, and several gram-negative organisms, including *Pseudomonas*. Humoral immunity usually is not as important in defending against intracellular bacteria (mycobacteria), fungi, and protozoa, so recurrent infection with these organisms is usual. Since T-cell function is not affected, the body’s response to viral infection is normal.

**Transient Hypogammaglobulinemia of Infancy**

At birth, infants are protected from infection by maternal IgG antibodies that have crossed the placenta during fetal development. They are normally deficient in IgA, IgM, IgD, and IgE because these Igs do not normally cross the placenta. During the first 6 months of life, maternal antibody levels gradually decline as the infant’s humoral immune system gradually takes over antibody production, reaching adult levels by 1 to 2 years of age.

In infants with transient hypogammaglobulinemia of infancy (THI), there is a reduction in one or more serum Ig levels resulting in recurrent infection. Most commonly, infants are deficient in both IgG and IgA, but cases of decreased IgA alone or decreased IgG, IgA, and IgM have been reported. Symptoms of THI usually manifest as maternal IgG antibody levels decline during the first 6 months of life and the infant’s immune system is unable to synthesize adequate Ig on its own. The most frequently occurring clinical manifestations include upper respiratory tract infections, lower respiratory tract infections (including pneumonia), allergies, and allergic asthma. Treatment of THI is usually with prophylactic antibiotics, but some evidence exists that intravenous immunoglobulin (IVIG) may play a role in improving quality of life and stopping the cycle of infection often seen in these children. Most cases of THI resolve spontaneously by 3 years of age, but some persist into adolescence and are often associated with other primary immunodeficiency syndromes.

**Primary Humoral Immunodeficiency Disorders**

Primary immunodeficiency disorders that affect B-cell differentiation and antibody production are the result of impaired differentiation and maturation of lymphoid stem cells in the bone marrow. Immature or naive B cells expressing surface IgM (IgM+) leave the bone marrow and migrate into the peripheral lymphoid tissues. After antigen and T-cell stimulation, they undergo “class switching” where they lose surface IgM and express other Ig types such as IgG, IgA, or IgE secreting plasma B cells (Fig. 15.1). Primary humoral immunodeficiency disorders can interrupt the production of one or all of the Igs at any point along the differentiation and maturation cycle.

**X-Linked Agammaglobulinemia.** X-linked agammaglobulinemia (XLA) is an inherited, sex-linked, recessive disorder that affects 1 in 250,000 males. XLA is a primary humoral immunodeficiency that is caused by a defect in early B cell development leading to a severe decrease in the production, maturation, and survival of mature B lymphocytes. The end result is a profound hypogammaglobulinemia and severe susceptibility to infection. Affected males are prone to infections with encapsulated bacteria, such as *S. pneumoniae*, *H. influenzae* type b, *Giardia lamblia*, meningococcus, and various enteroviruses.

In 1993, the gene mutation for XLA was found to be on Xq21.3-Xq22, which encodes for an intracellular signal kinase, named Bruton tyrosine kinase (Btk). Btk is expressed during all stages of B cell development but has its primary function...
function in early maturation where it plays a role in pre–B cell receptor signaling pathways. The absence of Btk causes an arrest in B-cell development. Mutation in the Btk gene results in an absence of mature circulating B cells and plasma cells. T lymphocytes, however, are normal in number and function.

Most boys with XLA are asymptomatic at birth because of the presence of circulating maternal antibodies. Once these levels start to drop, affected males develop life-threatening infections that are unresponsive to antibiotic therapy. Diagnosis is based on demonstration of low or absent serum IgEs. Current therapy, which includes chronic administration of IVIG and prophylactic antibiotics, is only partially effective, expensive, and associated with severe long-term complications. New treatments are being tested that utilize gene therapy to promote B-lineage–specific Btk expression; these treatments have had some success.6

Common Variable Immunodeficiency. Another form of humoral primary immunodeficiency associated with impaired B-cell differentiation and antibody production is common variable immunodeficiency (CVID). All patients have low serum IgG levels, but some present with low IgA and/or low IgM as well, resulting in impaired antibody response to specific infections and vaccine challenge. CVID is a heterogeneous disorder, affecting males and females equally, and no one specific gene mutation has been identified. Patients with this disorder may present with inducible T-cell costimulator (ICOS) deficiency, CD19 deficiency, polymorphisms of Escherichia coli MutS % (MSH5), or transmembrane activator and calcium mobilizing ligand inhibitor (TACI) deficiency. The result of these mutations is a failure of class switching in naive B cells in the late maturation process.6 Normally, circulating B cells express surface IgM and IgD and, after antigen and T-cell stimulation in lymphoid tissues, lose these markers and express IgG, IgA, or IgE. Memory B cells will also express the surface marker CD27 or tumor necrosis factor receptor subfamily member 7 (TNFRSF7). Thus, people with CVID have a relatively normal number of nonfunctioning B lymphocytes. CD4 and or CD8 T lymphocytes are usually not affected, but in many patients, overall T-cell counts may be diminished, particularly as a result of loss of CD4+ naive T cells.22

Clinical manifestations of CVID can begin at any time of life (from very young to very old) and most commonly include recurrent bacterial and viral infections of the respiratory tract. Autoimmune disease (27%) is frequently seen in people with CVID and is associated with both a reduction in overall T regulatory cell counts and impaired function. The most frequently seen autoimmune disorders diagnosed are immune thrombocytopenic purpura and autoimmune hemolytic anemia (AIHA), but cases of aseptic nonerosive seronegative inflammatory arthritis, inflammatory bowel disease, and vasculitides have been reported. Approximately 10% of people will present with a lymphoproliferative disorder at some point in their lives including splenomegaly, lymphadenopathy, interstitial lung disease, and, at its worst, lymphoma, most commonly of the non-Hodgkin type.6

Treatment methods for CVID are similar to those used for other primary humoral immunodeficiencies, with IVIG being the mainstay of therapy. Anaphylaxis to IgA in the IVIG has been reported in people with CVID who are deficient in IgA. IgA-depleted IVIG is available, and its use has greatly reduced this risk.

Selective Immunoglobulin A Deficiency. Selective IgA deficiency (SIGAD) is the most common primary immunodeficiency disorder, affecting 1 in 200 to 1 in 900 people. The syndrome is characterized by moderate to marked reduction in levels of serum and secretory IgA. In the body, secretory IgA binds to and neutralizes intestinal pathogens and their toxic products, so IgA antibodies are normally not found in the bloodstream unless bacterial flora invasion has occurred. In most cases of SIGAD, clinical manifestations are mild to absent. However, in the fulminant form the deficiency leads to an increased susceptibility to infections, particularly those of the respiratory and lower respiratory systems. In people with SIGAD, B lymphocytes express surface IgA, but the cells appear to be developmentally arrested so that terminal differentiation into IgA-secreting plasma cells does not occur. The exact mechanism of IgA deficiency is unknown, but in many cases, genetic mutations in the TACI gene have been identified. Other pathophysiologic mechanisms postulated include the presence of IgA-specific T suppressor cells, inadequate T-helper cell function, or decreased expression of CD40 on the surface of monocytes. SIGAD is genetically linked to CVID; both disorders appear to be the result of the same molecular defect. Many children with SIGAD will go on to develop CVID later in life and vice versa. SIGAD occurs in both men and women and in members of successive generations within families. This suggests autosomal inheritance with variable expressivity because many people have a family history of either SIGAD or CVID. The majority of people with SIGAD have no overt symptoms because IgG and IgM levels are usually normal and the humoral response to infection is usually adequate. At least 50% of affected children overcome the deficiency by the age of 14 years. People with severe deficiencies often experience repeated respiratory and gastrointestinal infections and have an increased incidence of allergy and other autoimmune diseases. In people diagnosed with SIGAD, the frequency of circulating anti-IgA antibodies has been reported to be from 20% to 40%, so anaphylaxis and allergic reactions to blood products are of real concern to practitioners. Therefore, only specially washed erythrocytes from normal donors or erythrocytes from IgA-deficient donors should be used.

There is no definitive treatment available for SIGAD unless there is a comorbid reduction in IgG levels. Administration of IgA immune globulin is of little benefit because IgA has a short half-life and is normally confined to the mucosal layers. There also a significant risk of anaphylactic reactions associated with IgA antibodies in the immune globulin in patients that have circulating anti-IgA present in the bloodstream.

Immunoglobulin G Subclass Deficiency. IgG antibodies can be divided into four subclasses designated IgG1 through IgG4, based upon their underlying structure and function. People may present with deficiencies in one or more of the IgG subtypes, despite normal levels of overall serum IgG. Deficiencies
of IgG1 and IgG2 are most common and are more likely to be associated with low serum IgG levels because they are the major components of IgG antibodies.29 Most circulating IgG belongs to the IgG1 (70%) and IgG2 (20%) subclasses. In general, antibodies directed against antigenic protein belong to the IgG1 and IgG3 subclasses, whereas antibodies directed against carbohydrate and polysaccharide antigens are primarily of the IgG2 subclass. As a result, people who are deficient in IgG2 subclass antibodies may be at greater risk for development of sinusitis, otitis media, and pneumonia caused by polysaccharide-encapsulated microorganisms such as S. pneumoniae, H. influenzae type b, and N. meningitidis. However, decreased antibodies of one or more subclasses may be found in healthy people. Treatment of IgG subclass deficiency is dependent upon the specific deficiency and clinical presentation. Children with mild forms can be treated with prophylactic antibiotics to prevent repeated infections. IVIG can be given to children with severe manifestations of this deficiency.

Cell-Mediated (T Cell) Immunodeficiencies

Cell-mediated immunodeficiencies are a heterogeneous group of disorders that arise from defects in one or more components of the cell-mediated immune response. Whereas B lymphocytes undergo a definitive path of differentiation that culminates in antibody production, the functions of mature T lymphocytes are immunologically diverse. T lymphocytes are made up of two distinct subpopulations: CD4+ helper T cells and CD8+ cytotoxic T cells. The subpopulations of T lymphocytes work collectively to protect against fungal, protozoan, viral, and intracellular bacterial infections; control malignant cell proliferation; and coordinate the overall immune response. Therefore, defects in different components of the system can result in a wide range of immunologic responses.

Primary Cell-Mediated Immunodeficiency Disorders

Of all the primary immunodeficiencies, the T cell–mediated disorders are considered to be the most severe. Those affected succumb to serious viral, fungal, and opportunistic infections within the first few months of life.30,31 The presence of maternal antibodies offers no immunologic advantage against these cell-mediated disorders. Children with the most severe T cell–mediated defects, such as severe combined immunodeficiency disorder (SCID), rarely survive beyond infancy or childhood. Newly identified T-cell defects, such as the X-linked hyper-IgM syndrome, have a more favorable outcome with minimal to no treatment.

Primary T cell immunodeficiency disorders result from defective expression of the T-cell receptor (TCR) complex, defective cytokine production, and defects in T-cell activation. They impair the ability of the immune system to protect against fungal, protozoan, viral, and intracellular bacterial infections (CD8+ cytotoxic T cells).

Secondary Humoral Immunodeficiency Disorders

There are numerous causes of secondary hypogammaglobulinemia, including malnutrition, burns, gastrointestinal loss, nephrotic syndrome, malignancy, and as a side effect of certain medications.29 These conditions can result in an increase in Ig loss and/or a decrease in Ig production. For example, nephrotic syndrome is associated with loss of serum IgG as a result of abnormal glomerular filtration and subsequent urinary loss. Serum IgA and IgM remain normal or are slightly elevated because they are large molecular weight molecules that cannot be filtered by the glomerulus.29 In contrast, several malignancies such as leukemias and lymphomas are associated with antibody deficiencies because they decrease overall antibody production. Many commonly used medications can impair antibody levels by either mechanism and include several of the antiepileptics, antihypertensives, and glucocorticoids. The effects can usually be reversed by withdrawal of the medication.
therapy is becoming increasingly popular for the treatment of specific T-cell disorders including Wiskott-Aldrich syndrome (WAS), X-linked SCID, and adenosine deaminase (ADA) deficiency.\textsuperscript{32,33} The major risk to recipients of bone marrow and stem cell transplantation is that of graft versus host disease (GVHD).

**DiGeorge Syndrome.** DiGeorge syndrome or velocardiofacial syndrome is an embryonic developmental defect associated with chromosome 22q11.2 deletion.\textsuperscript{34,35} It occurs in approximately 1:4000 births. The incidence of this disorder is increasing because many of those now affected go on to give birth to affected children.\textsuperscript{34} The defect is thought to occur before the 12th week of gestation, when the thymus gland, parathyroid gland, and parts of the head, neck, and heart are developing. Children with DiGeorge syndrome present with a wide complex of defects including mild to moderate immunodeficiency resulting from a congenitally absent thymus, cardiac and renal anomalies, facial defects, hypoparathyroidism, skeletal defects, and developmental delays. The disorder affects both sexes.

The phenotypic expression of the chromosomal abnormality associated with DiGeorge syndrome is extremely variable. Infants born with this defect usually have partial or complete failure of development of the thymus and parathyroid glands and have congenital defects of the head, neck, palate, and heart. In some children, the thymus is not absent but is extremely small and located outside of the mediastinum. In these children, growth and development of the thymus may occur with normal stimulation of the immune system. The facial disorders can include hypertelorism (i.e., increased distance between the eyes); micrognathia (i.e., abnormally small jaw); low-set, posteriorly angulated ears with associated hearing loss; split uvula; a high-arched or cleft palate; and oro- and nasopharyngeal muscle weakness.\textsuperscript{36,37} In the majority of affected children, the palatal defects are associated with poor feeding, impaired speech quality, and delayed speech acquisition.\textsuperscript{36} Renal abnormalities affect approximately one third of children with DiGeorge syndrome. Fortunately renal dysplasia and agenesis are rare consequences requiring immediate dialysis. Hypocalcemia and tetany may develop within 24 hours of birth as a result of absent or hypoplastic parathyroid glands.

The immune system is affected in 75% of children with DiGeorge syndrome as a result of thymic hypoplasia.\textsuperscript{34} However, the size of the thymus does correlate directly with circulating T-cell counts because of the presence of a limited number of thymic cells in aberrant locations. As a result, the severity of T-cell dysfunction ranges from no circulating T cells to normal counts. Children with severe T-cell dysfunction are more prone to recurrent or chronic viral, fungal, and intracellular bacterial infections. Impaired helper T-cell function affects antigen presentation to B cells and subsequent antibody production. This phenomenon appears to be limited to children as there is no clinical evidence that adults have an increased risk of infection.

Treatment of DiGeorge syndrome is dependent upon the presenting symptoms. Cardiac anomalies are usually repaired shortly after birth. In children with true thymic aplasia and congenitally absent T cells, a thymus transplant or fully matched T-cell transplant is the treatment of choice to reconstitute T-cell immunity. As with any primary immunodeficiency, autoimmunity is a potential problem. Therefore, precautions must be taken during transplantation or transfusion therapy to prevent GVHD.

**X-Linked Immunodeficiency with Hyper-IgM.** The hyper-immunoglobulin M (HIGM) syndromes are a heterogeneous group of primary immunodeficiency disorders resulting from defective Ig class switch recombination during B-cell maturation leading to a deficiency in IgG, IgA, and IgE, but elevated levels of IgM.\textsuperscript{38} It is found only in males. Under normal conditions, class switch recombination is dependent upon antigen presentation to B cell receptors, which is mediated through direct T cell interaction and signal via the CD40 ligand/CD40 receptor.\textsuperscript{38,39} The disorder results from the inability of T cells to signal B cells to undergo isotype switching to IgG and IgA. Thus, they continue to express only the IgM subclass of IgGs. In most cases, it is the result of a genetic mutation resulting in a CD40 ligand deficiency.\textsuperscript{38,40} Although the disorder was identified on the basis of an antibody defect, its primary cause is a defect in cell-mediated immunity.

Clinical manifestations of HIGM occur early in life with a median age of onset at less than 12 months.\textsuperscript{38} Children usually present with recurrent sinopulmonary infections that may progress to bronchiectasis and pneumonia. In approximately 40% of cases, the presenting symptom is an opportunistic infection such as *Pneumocystis jiroveci* (PJP).\textsuperscript{40} Unfortunately, these children are at particular risk for the development of autoimmune disorders and malignancies of the biliary tree, intestine, and neuroendocrine system because of defects in CD40 signaling.\textsuperscript{38} Treatment is usually with Ig replacement and prophylactic antibiotic treatment.

**Secondary Cell-Mediated Immunodeficiency Disorders**

Secondary cell-mediated immunodeficiencies are more prevalent than primary deficiencies and are frequently associated with acute viral infections (e.g., measles virus, cytomegalovirus) and with certain malignancies such as Hodgkin disease and other lymphomas. Viral infections frequently impair cell immunity via direct infection of specific T-lymphocyte subpopulations (e.g., helper cells). Lymphotropic viruses such as HIV and human herpesvirus (HSV) type 6 selectively deplete the cell subtype that they invade, resulting in a concomitant loss of immunologic function associated with that subtype. People with malignancies can have impaired T-cell function because of either unregulated proliferation or depletion of a particular cell type. Some cases of T-cell immunodeficiency have no known etiology but are acquired later in life. Idiopathic CD4+ T-cell lymphocytopenia is a rare disorder characterized by a profound and persistent CD4+ T-cell defect that predisposes
to the development of severe opportunistic infections in the absence of other immune defects. Regardless of the etiology, people with secondary cell-mediated immune dysfunction may display an increased susceptibility to infections caused by normally harmless pathogens (i.e., opportunistic infections) or may be unable to mount delayed hypersensitivity reactions (i.e., anergy). People with anergy have a diminished or absent reaction to antigen even in the presence of known infection.

**Combined T-Cell and B-Cell Immunodeficiencies**

Combined T-cell and B-cell lymphocyte disorders manifest with defects in both the humoral and cell-mediated immune responses. Collectively these disorders are known as combined immunodeficiency syndrome (CIDS), but they are a diverse group caused by mutations in a multitude of genes that influence lymphocyte development or response, including lymphocyte receptors, cytokines, or major histocompatibility complex (MHC) antigens, that could lead to combined immunodeficiency. The end result is a disruption in the communication pathways between the cells of the humoral and cell-mediated immune systems and failure of the adaptive immune response. The spectrum of disease resulting from combined immunodeficiency disorders (CIDs) ranges from mild to severe to, ultimately, fatal forms.

**Severe Combined Immunodeficiency Disorders**

SCIDs are a group of genetically diverse disorders characterized by profound deficiencies of T and B lymphocytes, and in some forms NK, with the subsequent loss of both humoral and cellular immunities. The reported incidence of SCIDs is 1:100,000 live births, and they collectively account for approximately 20% of primary immunodeficiency disorders. Affected infants are lymphopenic and lack T cells, which normally constitute 70% of the total circulating lymphocytes. They have a disease course that resembles AIDS, with failure to thrive, chronic diarrhea, and the development of severe opportunistic infections. SCID is usually fatal within the first 2 years of life unless reconstitution of the immune system through bone marrow or hematopoietic stem cell transplantation can be accomplished. Early diagnosis is essential because the chances of successful treatment are better in infants who have not experienced severe opportunistic infections. Therefore, pediatricians and neonatologists are now advocating screening for SCIDs. Early receipt of hematopoietic stem cell transplant (HSCT) is associated with the greatest degree of long-term success. Enzyme replacement therapy and gene therapy are being investigated and have been met with some success in children with certain SCID subtypes.

To date, 13 different mutations have been linked to SCID. X-linked mutations account for almost 45% of all cases as a result of defects in the common gamma chain of the cytokine receptor. Mutations inherited as autosomal recessive traits account for the majority of the remaining cases of SCID including mutations in the genes that code for ADA, Janus kinase 3, the α chain of the interleukin-7 receptor, and RAG1 and RAG2. Many of these mutations result in defects that impair T-cell maturation including defects in cytokine receptor control of T-cell differentiation, antigen gene receptor arrangement on T and B cells, or any other component of T-cell antigen receptor function necessary for normal T-cell development.

The most common form of SCID is X-linked and is therefore more prevalent in males. It is caused by a genetic mutation in the IL2RG gene that codes for the common gamma-chain subunit (γc) of cytokine receptors. This transmembrane receptor is a shared element of several interleukin (IL) receptors, including the IL-7 receptor, which is responsible for proliferation of T-lymphocyte precursors. Impaired receptor function results in defective T-lymphocyte differentiation and production. Although the B cell production is unaffected, antibody production is impaired because of a lack of T-cell help.

ADA deficiency SCID is one of the most common forms of SCID inherited as an autosomal recessive trait. It accounts for 15% to 20% of all SCID cases, with reported prevalence rates ranging from 1:375,000 to 1:660,000 live births. ADA is a key enzyme in the purine pathway that catalyzes the irreversible deamination of adenosine to deoxyadenosine. Defects in the ADA gene cause an accumulation of toxic purine metabolites in the plasma and ultimate destruction of T cells. Soon after birth, infants present with profound lymphopenia (total count <500/mm³), an absence of cell-mediated and humoral immunity, recurrent infections, and failure to thrive. The systemic accumulation of toxic purine metabolites causes other end-organ effects in the lung, musculoskeletal and central nervous systems, the gastrointestinal tract, and the liver. Bone marrow transplantation from an HLA-identical sibling donor is the treatment of choice for children with ADA-SCID, but is feasible in only a minority of cases. Enzyme replacement therapy with pegylated bovine (PEG-ADA) has proven to be effective in approximately 70% to 80% patients but is frequently associated with incomplete immunological reconstitution because many patients develop anti-ADA antibodies.

The other less common causes of SCID are due to recombinase-activating gene (RAG) deficiencies, Janus kinase 3 (Jak3) deficiency, and mutations that impair the expression of class II MHC molecules. Defects in RAG activity are the result of mutations encoded on chromosome 11p13 and impair the somatic gene rearrangements necessary for the somatic rearrangement of antigen receptors on T and B cells. Jak3 is essential for signal transduction through the common γc. This is similar to the defect in X-linked SCID, and, therefore, the two disorders share many of the same underlying molecular defects. MHC II defects prevent the development of normal CD4+ helper T cells.

**Combined Immunodeficiency Disorders**

CIDs are less severe than those categorized as SCIDs because they present with diminished, rather than absent, T-cell
function and B-cell antibody production. Like SCID, the CIDs are a heterogeneous group of disorders with diverse genetic causes. They are often associated with other disorders such as ataxia–telangiectasia (AT) and WAS.

Like all primary immunodeficiencies, children with CID are prone to development of recurrent infections including pulmonary infections, skin, and urinary tract infections. They also have a higher incidence of chronic diarrhea and other gastrointestinal disorders, as well as gram-negative sepsis. Although they usually survive longer than children with SCID, without treatment they fail to thrive and often have a shortened lifespan.

**Ataxia–Telangiectasia.** AT is a rare autosomal recessive disorder caused by a gene mutation (ATM, ataxia–telangiectasia mutated) mapped to chromosome 11q22-23.54-55 ATM is a large serine/threonine kinase that is involved in the cellular response to breakage in the double strand of the DNA helix.56 It is a complex, multisystem disorder characterized by neurodegeneration, primarily of the cerebellum, and ocularcutaneous telangiectasia. Ataxia is the predominant neurodegenerative feature, which usually goes undiagnosed until the child begins to walk. It is associated with immune deficiencies including lymphopenia, hypogammaglobulinemia, and cell-mediated immune dysfunction that result in recurrent sinopulmonary infections. People with this disorder have an increased risk of cancer and radiation sensitivity. The most common malignancies that occur with this condition are lymphoid in origin, but solid tumors of the kidney (Wilms tumor) are frequently reported.56

Cognitive development is normal early in the disease process but levels off during childhood and ceases by 10 years of age. Children with AT have deficiencies of both cellular and humoral immunity. Overall lymphocyte counts are decreased, and there is a decrease in the ratio of CD4+ helper T cells to CD8+ suppressor T cells as well. Current research indicates that the primary defect in T-cell function is quantitative, not qualitative, because the existing T lymphocytes appear to be functionally intact.55 The majority of patients display Ig deficiencies in IgA, IgE, and IgG, with the IgG2 and IgG4 subclasses being most affected.56 Ninety-five percent of all affected children demonstrate elevated serum α-protein (AFP) levels.

**Wiskott-Aldrich Syndrome.** WAS is a severe and complex X-linked disorder characterized by thrombocytopenia, immunodeficiency, recurrent infections, eczema, and increased risk for the development of autoimmune disorders and lymphomas.57,58 The syndrome affects approximately 1 to 10 per million newborn males and is caused by mutations in the WAS gene. For children lacking WAS protein (WASP) expression, life expectancy is approximately 15 years.57,59 WASP is a key regulator of actin assembly in all hematopoietic cells (including platelets) in response to signals arising at the cell membrane.60 Hemorrhage, ranging from mild to life threatening, is common and occurs in over 80% of cases. Abnormalities of humoral immunity include decreased serum levels of IgM and markedly elevated serum IgA and IgE concentrations. This may be due to loss of T cell–mediated stimulation and an intrinsic inability of B cells to produce antibodies to T-independent polysaccharide antigens.57 T-cell dysfunction is initially limited but increases over time resulting in greater susceptibility to infection and the development of malignancies of the mononuclear phagocytic system, including Hodgkin lymphoma and leukemia.

Management of people with WAS focuses on treatment of eczema, control of infections, and management of bleeding episodes. Currently the only definitive treatment is allogenic HSC transplantation, but this is associated with considerable risk of complications including death and transplant rejection. HSC gene therapy is emerging as a promising therapeutic strategy since WASP expression is confined to hematopoietic cells. In clinical trials, patients infused with autologous CD34+ cells transduced with WASP-expressing retrovirus have demonstrated immunologic reconstitution.58

**Disorders of the Complement System**

The complement system is an integral part of the innate immune response and essential to the integrity of the immune system, including the adaptive immune response. Activation of the complement system occurs via one of three ways: the classic, lectin-mediated, or alternative pathways. Regardless of the pathway, activation of the complement system promotes chemotaxis, opsonization, and phagocytosis of invasive pathogens and bacteriolysis. Alterations in any component of the complement system can lead to enhanced susceptibility to infectious diseases and to the development of a host of autoimmune processes.

**Primary Disorders of the Complement System**

Primary disorders of the complement system can be transmitted as autosomal recessive, autosomal dominant, or autosomal codominant traits.10,61,62 In the case of codominance, heterozygotes usually have one functioning gene, and complement levels in most cases are sufficient to prevent disease. The majority of disorders associated with the complement system are the result of inappropriate activation and regulation of complement proteins, not necessarily deficiencies of complement proteins themselves.61 In fact, protein deficiencies of the classical and alternative pathways are rarely seen. Protein deficiencies of the lectin pathway, although more common, are not a major cause of primary complement disorders.

Primary disorders of the complement system can involve one or more proteins, receptors, and/or control molecules at any point along the complement cascade. However, the clinical presentation is dependent upon the component affected. For example, defects in the classical pathway result in an increased of autoimmunity and infection with high-grade pathogens, while defects in the lectin pathway are associated
with an increased risk of infection from unusual pathogens such as Cryptosporidium and Aspergillus. Since all three pathways converge at the activation of C3, defects that impact C3 or late-acting proteins affect activation of complement by all three pathways and are associated with marked increases in infection with high-grade pathogens, including Neisseria gonorrhoeae and Neisseria meningitides infection, hemolytic uremic syndrome, and adult-onset macular degeneration. It is now known that the complement system plays a key role in the control of the adaptive immune response. Subjects deficient in complement proteins frequently have significant defects in the adaptive immune response. C1q, C3, and C4 deficiencies are associated with a diminished immune response especially to T cell–dependent antigens. In addition, they have poor germinal center activity and poor immunologic memory. In the C1 subunit, C1q is essential for the binding of immune complexes and apoptotic cells, promoting their eventual removal from the circulation.10 These patients, therefore, have an increased risk of infection from encapsulated bacteria, particularly S. pneumoniae. In addition, they are at increased risk for the development of autoimmune disease processes, particularly systemic lupus erythematosus (SLE) and other forms of vasculitis.20

Defects in the lectin pathway have just recently been defined to involve the essential protein mannose-binding lectin (MBL). MBL does not require antibody presentation for activation, as does C1 in the classic pathway. MBL possesses a central core and radiating arms with an intertwined, chained collagen structure capable of binding bacterial surface polysaccharides. A single gene defect that is carried as an autosomal dominant trait results in improper binding of the MBL molecule and abnormally low plasma concentrations (<2 μg/mL). The majority of the complement disorders are the result of defects in complement control receptors and molecules. Since tight regulation of C3 is essential to prevent host tissue damage, a host of substances and receptors play a role in the process. Deficiency or improper activation can cause significant disease despite normal circulating complement protein levels. Under normal circumstances the binding of C3b to a target serves two functions, continuation of the complement cascade and opsonization. Factor H and factor I are essential for the inactivation of C3b in the plasma and on erythrocytes. Factor H is a cofactor for the cleavage of C3, and complete deficiencies are associated with glomerulonephritis, atypical hemolytic uremic syndrome (aHUS), age-related macular degeneration, and HELLP (hemolytic anemia, elevated liver enzymes, low platelets) syndrome during pregnancy. Factor I is a cofactor for the cleavage of both C4 and C3. Complete deficiency is associated with low circulating C3 and opportunistic infection. Hereditary Angioneurotic Edema. Hereditary angioedema (HAE) is a rare, life-threatening complement disorder that results from a quantitative (type I) or qualitative (type II) deficiency of C1-inhibitor (HAE-C1-INH). HAE is inherited as an autosomal dominant trait that causes mutations in the SERPING1 gene located in the q12-q13.1 region of chromosome 11. In the complement system, C1-INH normally inhibits activated C1r and C1s in the classic pathway as well as the early steps in the lectin pathway. It also functions as an inhibitor of the coagulation, fibrinolytic, and kinin-generating pathways through the inactivation of plasma kallikrein and factor XIIa. Deficiencies in C1-INH result in the uncontrolled release of various vasoactive substances that promote vascular permeability. The net result is the development of spontaneous episodes of deep localized tissue swelling in the subcutaneous tissues of the extremities, face and torso, or the submucosal tissues of the upper airway and gastrointestinal tracts. Laryngeal edema is a life-threatening manifestation that can lead to complete airway obstruction and death without intervention. Swelling of the structures of the gastrointestinal mucosa is associated with severe nausea, vomiting, and diarrhea. In some patients attacks may be preceded by the development of erythema marginatum, a macular, pruritic erythematous rash. HAE usually manifests during early childhood and progresses in severity into adolescence. Symptoms usually peak in 1.5 days and then resolve over the same time frame. Management of the disorder involves emergency management in cases of severe airway obstruction including emergency intubation or tracheotomy, C1-INH concentrate, bradykinin receptor B2 antagonists, or kallikrein inhibitor. Preventative treatment usually involves the avoidance of precipitating influences, the administration of attenuated androgens and antifibrinolytics, or C1-INH concentration.

Secondary Disorders of the Complement System
Secondary complement deficiencies occur as a result of rapid activation or turnover of complement components in the face of normal complement levels as seen in immune complex disease. They are also seen in cases of chronic liver disease and malnutrition where complement protein production is negatively impacted. Regardless of the cause, the manifestations of secondary disorders are dependent upon the components of the complement pathways affected.

Disorders of Phagocytosis
The phagocytic system is composed primarily of polymorphonuclear leukocytes (i.e., neutrophils and eosinophils) and mononuclear phagocytes (i.e., circulating monocytes and tissue and fixed macrophages). These cells are primarily responsible for the removal of microorganisms, toxins, and cellular debris from the body. When activated by chemotaxic factors, phagocytic cells migrate to the site of action and envelope the invading microorganisms or foreign substances. In addition, they produce microbicidal substances such as enzymes and metabolic by-products that kill or ingest pathogens. Following resolution of an infection process, phagocytic cells (e.g., neutrophils) undergo programmed cell death or apoptosis,
order to prevent damage to host cells as a result of exposure to activated microbicidal proteases and chemotactic substances. A defect in any of these functions or a reduction in the absolute number of available cells can disrupt the ability of phagocytic system to function effectively. People with phagocytic disorders are exquisitely susceptible to bacterial and fungal infections including *Candida*. However, the exact pathogen varies with the particular disease process. As with other alterations in immune function, defects in phagocytosis can be primary or secondary disorders.

**Primary Disorders of Phagocytosis**

Primary disorders of phagocytosis affect leukocyte adhesion (*e.g.*, leukocyte adhesion deficiency or LAD), microbicidal production and activity (*e.g.*, chronic granulomatous disease [CGD]), and the process of cellular degranulation (*e.g.*, Chédiak-Higashi syndrome [CHS]).

LADs are a group of rare genetic disorders (≤1: 1,000,000 births) that share a common defect in neutrophil adhesion. Currently three distinct genetic mutations in chromosome 21q22.3 have been linked to the development of LAD. These mutations alter neutrophil CD18 expression resulting in defective chemotaxis, margination, and adherence. In addition, there is a decrease in NK cell and cytotoxic T-cell function. During early stages of an infection, neutrophil adherence to postcapillary endothelium is weak because of rolling selectin interactions. As the immune response mounts, β-integrin interactions strengthen the adherence and allow neutrophils to migrate into surrounding tissues. Clinically relevant defects can occur at any point in this process.

LAD-1 is the most common form of the disorder resulting from deficiencies in the CD18 integrin necessary for surface expression of CD11/CD18. Patients with LAD-1 typically present with one of two phenotypes, but all present with recurrent, life-threatening bacterial infections and nonhealing ulcers that are often misdiagnosed as ulcerative colitis. People with the most severe forms of the disease have less than 1% of normal CD18, and approximately 75% die before the age of 2 unless they undergo stem cell transplantation. LAD-II results from a defect in fucose metabolism, which is responsible for the absence of fucosylated glycans on cell surface membranes and selectin-mediated adhesion. LAD-III appears to be the result of failed activation of several of the integrins necessary for CD18 expression.

**Chronic granulomatous disease** (CGD) is one of the most common forms of primary phagocyte dysfunction affecting approximately 1: 200,000 births. It results in an increased susceptibility to both bacterial and fungal infections as well as the development of granulomatous lesions. CGD is characterized by defects in microbicidal oxidant production, specifically the superoxide-generating phagocyte oxidases known as *phox* that render affected individuals unable to phagocytize microorganisms. Six different subunits derived from nicotinamide adenine dinucleotide phosphate oxidase complex make up the *phox* oxidase molecule. Each is found separately in the cytoplasm or in membrane vesicles in resting neutrophils. Upon neutrophil stimulation these subunits normally come together to form active oxidases at the phagosome membranes, creating an intracellular environment capable of killing ingested microbes. In people with CGD, mutations exist in the genes that encode for essential components of the *phox* subunits that result in the production of inactive *phox*. Four different genetic forms of CGD exist with 75% of cases inherited as an X-linked trait (mutations is the gp91*phox* subunit). Therefore, the majority of cases are diagnosed in males.

Children with CGD are subject to chronic and acute infections including pneumonia, subcutaneous and organ abscesses, cellulitis, osteomyelitis, sepsis, and supplicative adenitis despite aggressive prophylactic and therapeutic antibiotic therapy. These infections usually begin during the first 2 years of life. A wide range of fungi and bacteria are responsible for the infections including *S. aureus, Burkholderia cepacia, Burkholderia pseudomallei, Serratia marcescens, Escherichia coli, Candida albicans, Granulibacter bethesdensis*, and *Aspergillus* species. Chronic infection and inflammation result in the development of fibrotic granulomatous masses that may require eventually require surgical excision or that cause end-organ damage. Cognitive defects are also associated with CGD, but the exact mechanism is unknown. Bone marrow transplantation is the only known cure for CGD. Supportive care includes the use of recombinant interferon-gamma and prophylactic antibiotic therapy.

**Chédiak-Higashi syndrome** (CHS) is a rare (<500 cases) autosomal recessive disorder characterized by severe immuno-deficiency, increased susceptibility to infection, bleeding tendency, partial oculocutaneous albinism, and progressive neurologic dysfunction. Abnormally large, dysfunctional granules are readily seen in blood and bone marrow granulocytes and other cells including melanocytes, fibroblasts, endothelial cells, Schwann cells, and neurons. CHS is caused by mutations in a single gene located on chromosome 1q42-43, which encodes for the lysosomal trafficking regulator (LYST). Effected cells exhibit defective chemotaxis, reduced mobilization, microtubular activity and decreased bactericidal activity.

CHS manifests itself during infancy and early childhood, and few people survive into their teenage years. Sometime after the initial onset of infection, 50% to 85% of people enter into an “accelerated phase,” which is characterized by lymphocytic infiltration of the major organs of the body. While the organisms responsible for the infections seen in CHS are usually bacterial, the trigger for the accelerated phase appears to be a reaction to a viral infection, probably with the Epstein-Barr virus (EBV). People with CHS are unable to clear the EBV infection, which leads to a state of constant lymphoproliferation, end-organ failure, and death. Prophylactic treatment of CHS is symptomatic and includes antibiotics, but unfortunately does not prevent any of the complications from developing. Allogeneic hematopoietic cell transplantation continues to be the treatment of choice to restore hematologic and immunologic function, but does not prevent or reverse any of the other associated complications.
Secondary Disorders of Phagocytosis

Secondary deficiencies of the phagocytic system can result from a multitude of disorders including leukemia, malnutrition, viral infections, or diabetes mellitus. People with diabetes mellitus are more prone to develop poor phagocytic function because of altered cellular chemotaxis. The exact mechanism of the dysfunction is not known, but it does not appear to be associated with age or the severity of the endocrine disorder. There is some evidence that phagocytic dysfunction is coinnherited at a higher rate in people with diabetes. Drugs that impair or prevent inflammation and T-cell function, such as corticosteroids or cyclosporine, also alter phagocytic response through modulation of cytokines.

Stem Cell Transplantation

For most of the primary immunodeficiency disorders, hematopoietic stem cell transplantation (HSCT) from allogeneic human leukocyte antigen (HLA)-compatible sibling donors is the treatment of choice because it results in effective immunologic reconstitution and improved survival in approximately 90% of people. However, in less than 20% of cases can HLA compatible (i.e., matched for at least three of the six HLA loci) donors be found. For these people, transplants are performed utilizing mismatched family or matched unrelated donor (MUD) cells. However, a significant fraction of these people go on to develop delayed, suboptimal, or short-term immunologic reconstitution. They are also more prone to complications of HSCT such as GVHD, autoimmunity, chronic inflammation, and persistent infection. This had led to the development of newer therapies that incorporate gene therapy and immunologic preconditioning into the regimen.

Hematopoietic stem cells can be harvested from either the bone marrow or the peripheral blood. However, since the introduction of peripheral blood stem cell transplantation (PBSCT) in 1986, blood cells have replaced bone marrow in approximately 100% of autologous and 75% of allogeneic transplantations. For transplantation to be effective, myeloablative doses of chemotherapy have been traditionally administered in order to completely suppress host bone marrow function. However, recent research has demonstrated impaired long-term immune reconstitution in a significant proportion of these people. It appears that a stable mixed chimerism of donor cells in all lineages, including B and myeloid cells, is essential for long-lasting reconstitution. Newer, non-myeloablative chemotherapeutic conditioning regimens are designed to make room in the bone marrow for donor cells, without completely wiping out bone marrow function and are associated with better short-term and long-term survival rates.

The introduction of gene therapy has radically changed the face of stem cell transplantation. It has allowed the utilization of genetically altered autologous cells to correct preexisting cellular dysfunction. Retroviral vectors carrying the appropriate genetic code are transduced into peripheral blood cells, which are then transplanted back into the host. Depending upon the genetic vector, these genetically altered cells demonstrate sustained engraftment, with multilineage differentiation, increased cell counts, and improvement in both cellular and humoral functioning, without the risk of GVHD and other autoimmune disorders.

A third potential source of stem cells is umbilical cord blood. Umbilical cord blood is a rich source of primitive hematopoietic blood that can be collected at the time of delivery. Up to 250 mL of umbilical cord blood can be collected without producing detrimental effects to the mother and newborn. Although reliable engraftment of bone marrow can be achieved in children, it is uncertain whether cord blood contains enough stem cells for effective and sustained engraftment in adult transplant recipients.

IN SUMMARY

The immune response is a complex, multidimensional process that requires coordinated activities of both the innate and adaptive immune systems. Because of its complexity, it is not uncommon for one or more normal processes to become disrupted. An immunodeficiency is defined as an absolute or partial loss of the normal immune response that places a person at risk for the development of infection or malignancy. Disorders of the immune system can be classified as primary or secondary disorders. Primary disorders are inherited, as the underlying genetic defect is present at birth, while secondary disorders develop sometime later in life in response to another disease entity or condition. The extent to which any or all of these components are compromised dictates the severity of the immunodeficiency.

Immunodeficiency disorders can affect any component of the cellular or humoral immune response. B-lymphocytic or humoral immunodeficiency disorders can affect all circulating Igs, resulting in agammaglobulinemia, or target a single Ig (e.g., IgA immunodeficiency). Defects in humoral immunity increase the risk of recurrent pyogenic infections but have limited impact on the defense against intracellular bacteria (mycobacteria), fungi, protozoa, and most viruses, except those that cause gastrointestinal infection. T cell immunity is responsible for protection against fungal, protozoan, viral, and intracellular bacterial infections; for control of malignant cell proliferation; and for the coordination of the overall immune response. T-lymphocyte or cell-mediated immune disorders can present as selective T-cell immunodeficiency states or as combined T- and B-cell immunodeficiency disorders. Children born with SCID present with severe opportunistic infections and have a disease course that resembles AIDS. The majority of these children die before the age of one unless immune system reconstitution can be achieved through hematopoietic stem cell transplantation.

The complement system and phagocytic cells are integral components of innate immunity and can also be targeted in immunodeficiency disorders. The complement
system plays a key role in promoting chemotaxis, opsonization, and phagocytosis of invasive pathogens. Deficiencies in complement proteins, control molecules, or receptors can lead to enhanced susceptibility to infectious diseases and autoimmune disorders, particularly SLE. People with phagocytic disorders are exquisitely susceptible to bacterial and fungal infections including *Candida*; however, the exact pathogen varies with the particular disease process. Primary disorders of phagocytosis include LAD disorders, degranulation abnormalities, and defects in microbicidal activity.

**HYPERSENSITIVITY DISORDERS**

After completing this section of the chapter, you should be able to meet the following objectives:

- Describe the adaptive immune responses that protect against microbial agents and hypersensitivity responses.
- Discuss the immune response involved in the development of type I, type II, type III, and type IV hypersensitivity reactions.
- Describe the pathogenesis of common hypersensitivity reactions including allergic rhinitis, food allergy, serum sickness, Arthus reaction, contact dermatitis, and hypersensitivity pneumonitis.

Activation of the immune system normally results in the mobilization and coordination of T-cell and B-cell activity in order to protect the body from invading microorganisms and toxic substances. Unfortunately, this same system is capable of causing serious damage when it does not function as intended. Hypersensitivity is defined as an abnormal and excessive response of the activated immune system that causes injury and damage to host tissues. Disorders caused by immune responses are collectively referred to as hypersensitivity reactions. Hypersensitivity reactions are classified as one of four types: type I, IgE-mediated disorders; type II, antibody-mediated disorders; type III, complement-mediated immune disorders; and type IV, T cell-mediated disorders (Table 15.1). They differ with respect to the specific components of the immune response initiated, the onset of symptoms, and the eventual mechanism of injury.

**Type I, Immediate Hypersensitivity Disorders**

Type I hypersensitivity reactions are IgE-mediated reactions that develop rapidly upon exposure to an antigen. Type I hypersensitivity reactions represent the classic allergic response, and in this context, antigens are referred to as *allergens*. Environmental, medical, and pharmaceutical allergens are all capable of initiating a type I hypersensitivity reaction. Common allergens encountered include pollen proteins, house dust mites, animal dander, foods, household chemicals, and pharmaceutical agents like the antibiotic penicillin. Exposure to the allergen can be through inhalation, ingestion, injection, or skin contact. Depending on the portal of entry, type I reactions may be localized to a discrete area of the body (e.g., contact dermatitis) or systemic causing significant disease (e.g., asthma) and life-threatening anaphylaxis.

Two types of cells play a key role in the development of a type I hypersensitivity reactions: type 2 helper T (T₂H) cells and mast cells or basophils. Two distinct subtypes of helper T cells (T₁H or T₂H) develop from activated CD4⁺ helper T cells based upon the cytokines expressed by the antigen-presenting cells (APCs) at the site of activation. Macrophages and dendritic cells direct the maturation of CD4⁺ helper T cells toward the T₁H subtype, whereas mast cells and T cells induce differentiation toward the T₂H subtype. The T₁H cells stimulate the differentiation of B cells into IgM- and IgG-producing plasma cells. The T₂H cells direct B lymphocytes to switch class and produce the IgE antibodies necessary for an allergic or hypersensitivity response. In addition, T₂H cytokines are responsible for the mobilization and activation of mast cells, basophils, and eosinophils, inducing inflammatory responses that are distinct from T₁H reactions.

Mast cells, basophils, and eosinophils are essential to the development of type I hypersensitivity reactions. They are members of the *granulocyte* class of leukocytes because they contain granules rich in chemical mediators such as histamine and heparin. These mediators may be preformed or are enzymatically activated in response to T₂H signaling. Once they are released they are capable of inducing a wide range of cellular responses. Mast cells and basophils are histologically similar and derived from CD34⁺ progenitor cells. However, basophils are confined to the bloodstream, and mast cells are distributed throughout connective tissue, especially in areas beneath the skin and mucous membranes of the respiratory, gastrointestinal, and genitourinary tracts and adjacent to blood and lymph vessels. This places the mast cells in close proximity to surfaces with frequent exposure to allergen. Mast cells in different parts of the body and even in a single site can have significant differences in mediator content and sensitivity to agents that produce mast cell degranulation.

Type I hypersensitivity reactions are dependent upon IgE-mediated activation of mast cells and basophils (Fig. 15.2). During the initial exposure to an antigen, allergen-specific IgE is produced as part of the normal humoral response and IgE to the high-affinity IgE receptors known as FcεRI, expressed on the surface of mast cells and basophils. In contrast, lymphocytes, eosinophils, and platelets bind IgE via low-affinity FcεRII receptors. On subsequent exposure to an allergen, the multimeric cross-linkages between IgE antibodies are formed creating a bridge between two IgE molecules. When IgE receptors aggregate, they induce a signal transduction that stimulates mast cell degranulation and release of vasoactive chemical mediators, the
synthesis and secretion of platelet-activating factor (PAF) and leukotrienes, and the secretion of many growth factors, cytokines, and chemokines.

Most type I hypersensitivity reactions such as bronchial asthma develop in two distinct and well-defined phases: (1) a primary or initial-phase response characterized by vasodilation, vascular leakage, and smooth muscle contraction and (2) a secondary or late-phase response characterized by more intense infiltration of tissues with eosinophils and other acute and chronic inflammatory cells as well as tissue destruction in the form of epithelial cell damage.

The primary or initial-phase response usually begins with 5 to 30 minutes of exposure to an allergen and subsides within 60 minutes. It is mediated by acute mast cell degranulation and the release of preformed and/or enzymatically activated mediators. These mediators include histamine, serotonin, acetylcholine, adenosine, chemotactic mediators, growth factors, and neutral proteases such as chymase and trypsin that lead to generation of kinins. Histamine is the most recognized mediator of type I hypersensitivity reactions. It is a potent vasoactive amine that increases nitric oxide production, relaxes vascular smooth muscle, increases the permeability of capillaries and venules, and causes smooth muscle contraction and bronchial constriction. Acetylcholine mimics many of the actions of histamine and produces bronchial smooth muscle contraction and dilation of small blood vessels via activation of the parasympathetic nervous system. The kinins are a group of potent inflammatory peptides that once activated through enzymatic modification, produce vasodilation and smooth muscle contraction as well.
Chapter 15  Disorders of the Immune Response  

The secondary or late phase of the type I hypersensitivity response occurs 2 to 8 hours after resolution of the initial phase and can last for several days. In some cases, the late phase may be significantly prolonged or only partially resolved as in the case of uncontrolled bronchial asthma. It results from the action of lipid mediators and cytokines released from immune cells as part of the normal inflammatory process. The lipid mediators, which are derived from phospholipids found in mast cell membranes, are broken down to form arachidonic acid during the process of mast cell degranulation. Arachidonic acid is then utilized in the synthesis of leukotrienes and prostaglandins, which produce end-organ effects similar to histamine and acetylcholine, except that they have a longer onset and prolonged duration of action. Mast cells also produce cytokines and chemotactic factors that promote migration of eosinophils and leukocytes to the site of allergen exposure, contributing to late-phase response.

It is important to point out that not all IgE-mediated reactions result in hypersensitivity or the development of disease. The IgE-mediated antibody response is a normal part of the immune response to parasitic infection. During the late phase of the response, IgE antibodies are directed against parasite larvae stimulating recruitment of large bodies of inflammatory cells including eosinophils and causing cell-mediated cytotoxicity. This type of type I hypersensitivity reaction is particularly important in developing countries where much of the population is infected with intestinal parasites.

Anaphylactic (Systemic) Reactions
Anaphylaxis is a catastrophic, systemic life-threatening IgE-mediated hypersensitivity reaction associated with the widespread release of histamine into the systemic circulation that produces massive vasodilation, hypotension, arterial hypoxia, and airway edema. It results from the presence of even minute quantities of allergen that are introduced into the body via the airway, skin, blood, or gastrointestinal mucosa. The level of severity, therefore, depends on the preexisting degree of sensitization and not with the quantity of exposure.

Clinical manifestations occur along a continuum in severity and can be graded on a scale of I to IV. Grade I reactions are usually confined to the cutaneous and mucosal tissues manifesting as erythema and urticaria, with or without angioedema. Grade II reactions progress to include moderate multisystem signs such as hypotension, tachycardia, dyspnea, and gastrointestinal disturbances (e.g., nausea, vomiting, diarrhea, abdominal cramping from mucosal edema). Grade III reactions become life threatening because of the development of bronchospasm, cardiac dysrhythmias, and cardiac collapse. Once a hypersensitivity reaction reaches grade IV, cardiac arrest has occurred and management is purely resuscitative in nature.

Preventing exposure to potential triggers that cause anaphylaxis is essential because any reaction can be life threatening. All people with potential for anaphylaxis should be advised to wear or carry a medical alert bracelet, necklace, or other identification to inform emergency personnel of the possibility of anaphylaxis. In addition, people with a history of anaphylaxis should be provided with preloaded epinephrine syringes and instructed in their use.

The initial management of anaphylaxis is dependent upon the stage at which a person presents, but should always focuses on withdrawal of the offending allergen, maintenance of a patent airway, establishment of appropriate intravenous access, volume resuscitation, and administration of epinephrine. It is important to explain to all people with a potential for anaphylaxis that if they have a reaction and self-treat with epinephrine, it is essential for them to seek immediate professional help regardless of their initial response to self-treatment because reactions can reoccur.

Atopic (Local) Reactions
Local hypersensitivity reactions usually occur when the offending allergen is confined to a particular site of exposure. The term atopy is frequently used to describe these reactions and refers to a genetic predisposition to the development of immediate, type I IgE-mediated hypersensitivity reactions upon exposure to common environmental antigens such as pollens, food, or animal dander. Atopic reactions most commonly manifest as urticarial (hives), allergic rhinitis, atopic dermatitis, and bronchial asthma. People prone to atopy frequently develop reactions to more than one environmental allergen with symptoms present at different times throughout the year.

The incidence of immediate hypersensitivity reactions tends to be greater in people with a family history of atopy, yet the genetic basis for these disorders is not completely understood. Because of underlying genetic differences in people with type I hypersensitivity, the exact genome has been difficult to delineate. However, several chromosomal regions have been shown to contain gene sequences linked to the development of asthma and atopy, including the cytokine cluster on chromosome 5q, IFNG (IFNg) and STAT6 on 12q, and IL4 on 16p. People with atopic allergic conditions tend to have high total serum and allergen-specific levels of IgE as well as increased numbers of eosinophils, basophils, and mast cells. Although the IgE-triggered response is likely a key factor in the pathophysiology of atopic allergic disorders, it is not the only factor and may not be responsible for the development of all forms of atopic dermatitis and asthma.

Allergic Rhinitis. Allergic rhinitis is a common hypersensitivity disorder of the upper respiratory tract that affects between 20% and 40% of the western population. Symptoms include rhinorrhea (runny nose), nasal obstruction, sneezing, nasal itching, and watery eyes (conjunctivitis). The diagnosis of allergic rhinitis is made based upon the person’s clinical presentation and a positive skin prick test or the presence of serum-specific IgE antibodies to aeroallergens. People with allergic rhinitis frequently present with others forms of atopy such as allergic asthma and urticaria. Severe attacks may be accompanied by systemic malaise, fatigue, headache, and muscle soreness from sneezing. Fever is absent. The allergens...
associated with the development of allergic rhinitis are airborne and are therefore deposited directly onto the nasal mucosa. Typical allergens include pollens from ragweed, grasses, trees, and weeds; fungal spores; house dust mites; animal dander; and feathers.

Clinical manifestations are dependent upon the timing and severity of exposure. In people who are chronically exposed to allergens, symptoms can be present throughout the year. This form of atopy is known as perennial rhinitis. In contrast, people who present with symptoms only when exposed to high allergen counts, such as in the fall or spring, are said to have seasonal allergic rhinitis. Symptoms that become worse at night suggest a household allergen, and symptoms that disappear on weekends suggest occupational exposure.

The allergic response in allergic rhinitis is located specifically in the nasal mucosa. When Aeroallergens are inhaled, they are deposited mainly on the nasal mucosa where they are presented to T cells by APCs. In the presence of cellular cytokines, B-cell class switching occurs, resulting in an increase in IgE production. Once the allergen–IgE complex is formed, infiltration of the nasal mucosa by TH cells, mast cells, basophils, eosinophils, and Langerhans cells takes place, inducing a full cell-mediated immune response.

Treatment of allergic rhinitis focuses on the institution of avoidance measures and control of symptoms. Whenever possible, the offending allergen should be removed from the environment, or exposure should be kept to a minimum. Most symptoms can be controlled with over-the-counter antihistamines and topical nasal decongestants. Tolerance and rebound congestion may occur with chronic administration of topical nasal decongestants, so their use should be limited to less than 1 week. More severe symptoms may require prescription medication including topical nasal corticosteroids (e.g., mometasone or Nasonex) and antihistamines (e.g., azelastine HCI). Mast cell stabilizers, such as intranasal cromolyn sodium, that prevent localized mast cell degranulation and release of intracellular mediators may be useful, especially when administered prophylactically. In people whose symptoms cannot be successfully controlled with these measures, a program of desensitization known as immunotherapy (“allergy shots”) may be undertaken. Desensitization involves the frequent administration of progressively larger quantities of the offending antigen(s). The antigens stimulate production of high levels of IgG antibodies, which are capable of combining with the antigen and preventing activation of cell-bound IgE antibodies.

**Food Allergies.** Food allergy is very common in western countries around the world, often manifesting with life-threatening consequences. In fact, food-induced anaphylaxis is the leading cause of emergency room admissions, especially among children. Currently, the prevalence rate of food allergy is between 3% and 6%, and, according to the Centers for Disease Control (CDC), this represents an increase of 18% over the past decade. The exact etiology of the increase in cases is unknown. Any food is capable of inducing a hypersensitivity reaction in susceptible people, but the most commonly implicated foods include peanuts, tree nuts, and shellfish. In addition, milk is frequently implicated in children. People with asthma, adolescents, and those with a personal or family history of food allergy are at increased risk of severe reactions.

The clinical manifestations of food allergy are dependent upon many factors including the amount of food ingested, the presence of an empty stomach, concurrent illness and medication, exercise, and the phase of the menstrual cycle. Reactions may differ within a given person during different exposures, but the primary symptoms are seen in the skin, gastrointestinal tract, and respiratory system in approximately 80% of cases. The ability of a specific food to trigger a type I hypersensitivity reaction may be changed during the cooking process because heating can alter (denature) the protein structure of an allergen, so that it is no longer able to trigger the humoral response. Both acute reactions (hives and anaphylaxis) and chronic reactions (asthma, atopic dermatitis, and gastrointestinal disorders) to food allergens can occur.

Anaphylactic reactions to food allergens are common, and the presentation may differ between adults and children. Adults typically present with severe symptoms including cardiovascular collapse, whereas severe abdominal pain, hives, allergic rhinitis, conjunctivitis, and facial flushing are more common in children. Within the pediatric population, wheezing and stridor are more common in preschoolers and older children, while hives and vomiting are usually seen in infants. The majority of the reactions manifest within 1 hour of exposure, but delayed reactions are possible secondary to delayed absorption of the allergen. A rare form of anaphylaxis associated with food is known as food-dependent exercise-induced anaphylaxis (FDEIA). In FDEIA, both exercise and the food allergen are tolerated independently, and symptoms do not occur in the absence of exercise. The pathophysiology is not completely understood but seems to suggest that a pliable state of immunologic tolerance exists in susceptible people. Alterations in plasma osmolality and pH, tissue enzyme activity, blood flow distribution, and gastrointestinal permeability may occur during exercise, which result in facilitated allergen recognition and binding.

Food allergies can occur at any age, but tend to manifest during childhood. The allergic response is activated when a specific food allergen comes in contact with IgE antibody present in the intestinal mucosa and subsequently stimulates local and systemic release of histamine and other cytokines necessary in the allergic response. Carbohydrates, lipids, proteins, or food additives, such as preservatives, colorings, or flavorings, can all serve as potential allergens in the allergic response. Cross-sensitivity to allergens between foods in closely related food groups is common. Therefore, a person can contain common cross-reacting allergens. For example, some people are allergic to all legumes (i.e., beans, peas, and peanuts).

Diagnosis of food allergies is multifaceted and relies upon a careful food history and provocative diet testing. Provocative testing involves the systematic elimination of suspected allergen(s) from the diet for a time to see if the
symptoms disappear and then reintroducing the allergen(s) to the diet to determine if the symptoms reappear. Only one food should be tested at a time if definitive diagnosis is sought. Allergen-specific serum IgE levels can also be tested if the risk of provocative food testing is too great.

Treatment of food allergy focuses specifically on the avoidance of the offending allergen. However, this can be difficult, especially in people that are exquisitely sensitive to a particular food protein because foods (processed or fresh) may be contaminated with the protein during handling of the food. Foods that are prepared in the same processing plants that handle tree nuts may be potential allergen sources and, therefore, illicit an allergic response in susceptible people. As a result, warnings are placed on all goods processed in facilities that handle highly allergenic foods. People with severe allergies or a history of anaphylaxis should be educated to carry an EpiPen and to seek emergency care immediately after exposure.

**Type II, Antibody-Mediated Disorders**

Type II (antibody-mediated) hypersensitivity or *cytotoxic hypersensitivity* reactions are mediated by IgG or IgM antibodies directed against target antigens on specific host cell surfaces or tissues. The antigens may be either intrinsic, inherently part of the host cell, or extrinsic, incorporated into the cell surface upon exposure to a foreign substance or infectious agent. Thus, the tissues that express the target antigens determine the clinical manifestations of type II hypersensitivity reactions. These antigens are known as *tissue-specific antigens.*

There are four general mechanisms by which type II hypersensitivity reactions can be propagated, but regardless of the pathway, it is always initiated by the binding of IgG or IgM antibody to tissue-specific antigens. These mechanisms include complement-activated cell destruction, antibody-mediated cell cytotoxicity, complement- and antibody-mediated inflammation, and antibody-dependent modulation of normal cell surface receptors (Fig. 15.3).

**Complement-Activated Cell Destruction**

The destruction of target cells in type II hypersensitivity reactions can occur as a result of activation of the complement system via the classic pathway. First, formation of the membrane attack complex (MAC) by activation of C5-C9 allows the passage of ions, small molecules, and water into the cell, causing direct lysis of the cell. In addition, IgG and the complement fragment C3b act as opsonins by binding to receptors located

---

**FIGURE 15.3** Type II, hypersensitivity reactions result from binding of antibodies to normal or altered surface antigens. (A) Opsonization and complement- or antibody receptor-mediated phagocytosis or cell lysis through membrane attack complex (MAC). (B) Complement- and antibody receptor-mediated inflammation resulting from recruitment and activation of inflammation-producing leukocytes (neutrophils and monocytes). (C) Antibody-mediated cellular dysfunction, in which antibody against the thyroid-stimulating hormone (TSH) receptor increases thyroid hormone production, and (D) antibody to acetylcholine receptor inhibits receptor binding of the neurotransmitter in myasthenia gravis.
on the cell surfaces of macrophages. This process activates the macrophages, which then destroys the target cells by phagocytosis. Thus, activation of the complement system produces a twofold response that culminates in cell destruction.

In people with AIHA, autoantibodies target epitopes located on red blood cells. Erythrocytes coated with these autoantibodies are destroyed by phagocytes in the liver or spleen. Some, but not all, autoantibody types also induce phagocytosis and cell lysis via the complement system. The same process occurs in utero in the development of erythroblastosis fetalis or Rh incompatibility. Women who are Rh negative lack RhD antigen on their erythrocytes but produce anti-D antibodies. In the Rh-positive fetus, maternal anti-D antibodies will coat fetal red blood cells containing RhD, allowing them to be removed from the fetal circulation by macrophage- and monocyte-mediated phagocytosis.

Antibody-Dependent Cell Cytotoxicity

Antibody-dependent cell cytotoxicity (ADCC) incorporates components of both the innate and adaptive immune responses in the destruction of target cells, but is not dependent upon activation or utilization of complement proteins. Rather the mechanism relies upon the activity of nonspecific NK cells, but other cells such as macrophages and eosinophils have been implicated. The Fc-fragment of the IgG antibody binds to Fc receptor (FcγR) on the surface of the effector cell, and the variable fragment binds to the epitope on the target cell surface, causing release of chemotactic substances and destruction of the target cell. ADCC is a common antiviral mechanism. It has been implicated in the development of several autoimmune disorders including pemphigus vulgaris.

Complement- and Antibody-Mediated Inflammation

When antigens that are normally expressed on vessel walls or that circulate in the plasma are deposited on the surface of endothelial cells or extracellular tissues, the manifestations are the result of localized inflammation as opposed to cell destruction. The presence of antibody in the tissues activates the complement cascade, resulting in the release of activated complement proteins C3a and C5a, which in turn attracts neutrophils to the area and stimulates the deposition of complement protein C3b. Neutrophils bind to the Fc antibody fragment or to C3b, but rather than destroying cells via phagocytosis, undergo degranulation and release of chemical mediators (enzyme and oxidases) involved in the inflammatory response. Antibody-mediated inflammation is responsible for the tissue injury seen in Goodpasture disease, which is characterized by the presence of autoantibodies against the α3NC1 domain of collagen IV, an essential protein in the basement membranes of the kidneys and lungs. The antibody-mediated neutrophil activation causes the development of glomerulonephritis, acute renal failure, and hemorrhagic lung disease if immunosuppressive therapy is not initiated.

Antibody-Mediated Cellular Dysfunction

In some type II reactions, the binding of antibody to specific target cell receptors causes the cell to malfunction in some way, rather than initiating the process of cell destruction. The antibody–receptor complex that is formed modulates the function of the receptor by preventing or enhancing interactions with normal ligands, by replacing ligand and directly stimulating receptors, or by destroying the receptor entirely. The symptoms of type II hypersensitivity reactions caused by antibody-mediated cellular dysfunction are dependent upon the specific receptor(s) that are targeted. In Graves disease, autoantibodies, known as thyrotropin-binding inhibitory Ig, bind to and activate thyroid-stimulating hormone (TSH) receptors on thyroid cells, stimulating thyroxine production and the development of hyperthyroidism. In contrast, in myasthenia gravis, autoantibodies are directed toward the nicotinic acetylcholine receptors located on the motor end plates within the neuromuscular junction, where they block the action of acetylcholine and stimulate the destruction of the receptors, leading to decreased neuromuscular function.

KEY POINTS

ALLERGIC AND HYPERSENSITIVITY DISORDERS

- Type I hypersensitivity reactions are dependent upon IgE-mediated activation of mast cells and basophils and the subsequent release of chemical mediators of the inflammatory response.
- Type II (antibody-mediated) hypersensitivity or cytotoxic hypersensitivity reactions are mediated by IgG or IgM antibodies directed against target antigens on specific host cell surfaces or tissues and result in complement-mediated phagocytosis and cellular injury.
- Type III (immune complex) hypersensitivity is caused by the formation of antigen–antibody immune complexes in the bloodstream, which are subsequently deposited in vascular epithelium or extravascular tissues and which activate the complement system and induce a massive inflammatory response.
- Type IV (cell-mediated) hypersensitivity involves tissue damage in which cell-mediated immune responses with sensitized T lymphocytes cause cell and tissue injury. Although all are T cell mediated, the pathophysiologic mechanisms and sensitized T-cell populations involved differ.

Type III, Immune Complex-Mediated Disorders

Immune complex allergic disorders are caused by the formation of antigen–antibody immune complexes in the bloodstream, which are later deposited in vascular epithelium or...
acute glomerulonephritis. Diseases including 
(SLE) and systemic lupus erythematosus 
are responsible for the vasculitis seen in many autoimmune 
tors, is directly responsible for the injury. Type III reactions 
accompanied by the release of potent inflammatory media-
tinflammatory cells by immune complexes and complement, 
cells of the inflammatory response. The activation of these 
inflammatory response by activating complement and gener-
lation can produce damage in any end-organ vessels includ-
ing those feeding the renal glomerulus, skin, lung, and joint 
synovium. They can be generalized if the immune complexes 
are deposited in many organs or localized to a particular 
organ, such as the kidney, joints, or small blood vessels of 
the skin. Once deposited, the immune complexes elicit an 
inflammatory response by activating complement and gener-
ing foreign serum, such as horse serum, for the treatment of 
diptheria and scarlet fever. This antigen load was capable 
of stimulating the production of large quantities of immune 
complexes that were deposited in tissues causing activation 
of mast cells, monocytes, polymorphonuclear leukocyte, and 
platelets. Today, large volume injection of foreign proteins 
is rarely indicated, but a variety of drugs including beta-
lactam antibiotics and sulfonamides are capable of causing 
similar reactions.

Treatment of serum sickness usually is directed toward 
removal of the sensitizing antigen and providing symptom 
relief. This may include aspirin for joint pain and antihista-
mines for pruritus. Epinephrine or systemic corticosteroids 
may be used for severe reactions.

**Localized Immune Complex Reactions**

The *Arthus reaction* is a localized immune complex reaction 
associated with discrete tissue necrosis, usually in the skin. It 
caused by repeated local exposure to an antigen, where high 
levels of preformed circulating antibodies exist. Symptoms 
usually begin within 1 hour and peak within 6 to 12 hours of 
an exposure. Lesions are typically red, raised, and inflamed. 
Ulcers may often form at the center of the lesions because of 
the release of inflammatory cytokines. The mechanism of the 
Arthus reaction is not completely understood but is believed 
be the result of localized contact of injected antigen with 
circulating IgG antibody. This reaction is the prototypical 
model for the development of localized vasculitis associated 
with certain drug reactions in humans.

**Type IV, Cell-Mediated 
Hypersensitivity Disorders**

Type IV hypersensitivity reactions differ from type I to III 
hypersensitivity reactions in that they are cell-mediated 
and delayed, rather than antibody-mediated and immediate 
immune responses (Fig. 15.5). The cell-mediated immune 
response is normally the principal mechanism of defense 
against a variety of microorganisms, including intracellular 
pathogens such as *Mycobacterium tuberculosis* and viruses, 
以及其他extracellular agents such as fungi, protozoa, and 

---

**Systemic Immune Complex Disorders**

Serum sickness is a clinical syndrome that results from the 
formation of insoluble antigen–antibody immune complexes 
in the presence of antigen excess and subsequent general-
ized deposition in target tissues such as blood vessels, joints, 
and the heart and kidneys. The deposited immune complexes 
activate the complement cascade, increase vascular perme-
ability, and stimulate the recruitment of phagocytic cells. The 
net result is generalized tissue damage and edema. Clinical 
manifestations include rash, fever, generalized lymphade-
nopathy, and arthralgias, which usually begin approximately 
1 to 2 weeks after the initial antigen exposure and subside 
upon withdrawal of the offending agent. In previously sensi-
titized people, severe and life-threatening reactions have been 
reported. Serum sickness was first described in people receiv-
ing foreign serum, such as horse serum, for the treatment of 
diptheria and scarlet fever. This antigen load was capable 
of stimulating the production of large quantities of immune 
complexes that were deposited in tissues causing activation 
of mast cells, monocytes, polymorphonuclear leukocyte, and 
platelets. Today, large volume injection of foreign proteins 
is rarely indicated, but a variety of drugs including beta-
lactam antibiotics and sulfonamides are capable of causing 
similar reactions.

---

extravascular tissues (Fig. 15.4). The deposition of these 
xplexes in the tissues activates the complement system 
and induces a massive inflammatory response. Like type II 
hypersensitivity reactions, IgG and IgM antibodies activate 
immune complex–mediated disorders. However, in type III 
reactions, the antibody–antigen complexes are formed first 
in the plasma and then deposited in the tissues. The clinical 
manifestations may therefore have little to do with the par-
ticular antigenic target, but rather with the site of immune 
complex deposition. Immune complexes formed in the circu-
lation can produce damage in any end-organ vessels includ-
ing those feeding the renal glomerulus, skin, lung, and joint 
synovium. They can be generalized if the immune complexes 
are deposited in many organs or localized to a particular 
organ, such as the kidney, joints, or small blood vessels of 
the skin. Once deposited, the immune complexes elicit an 
inflammatory response by activating complement and gener-
ating chemotactic factors that recruit neutrophils and other 
cells of the inflammatory response. The activation of these 
inflammatory cells by immune complexes and complement, 
accompanied by the release of potent inflammatory media-
tors, is directly responsible for the injury. Type III reactions 
are responsible for the vasculitis seen in many autoimmune 
diseases including *systemic lupus erythematosus* (SLE) and 
acute glomerulonephritis.
parasites. However, it can cause cell death and tissue injury in sensitized people in response to topically administered chemical antigens (contact dermatitis), systemic antigen exposure, or as part of the autoimmune process.

Type IV hypersensitivity reactions are comprised of a spectrum of disorders that range from mild to severe in clinical presentation. Although all are T cell–mediated, the pathophysiologic mechanisms and sensitized T-cell populations involved differ. Because of the heterogeneity of delayed hypersensitivity reactions, current immunology experts subdivide type IV reactions into four distinct subtypes (IVa, IVb, IVc, and IVd) based upon the immune response, T-cell population, and pathologic characteristics involved. In addition, depending upon the reaction, different T-cell subsets with different cytotoxic and regulatory functions can be activated at different stages of the disease process.

In type IVa hypersensitivity reactions (e.g., eczema), the CD4⁺ T₁H cells activate monocytes and macrophages through the secretion of large amounts of interferon (IFN-γ). Activated monocytes stimulate the production of complement-fixing antibodies and activate proinflammatory (e.g., tumor necrosis factor [TNF]-α and interleukin [IL]-12) and CD8⁺ responses. Because type IVa responses require the synthesis of effector molecules, they can take up to 24 to 72 hours to develop, which is why they are called “delayed-type” hypersensitivity disorders.

Type IVb and IVd reactions are also considered to be delayed hypersensitivity reactions. Type IVb reactions (e.g., maculopapular exanthema and bullous exanthema) are the result of T₂H cell activation and eosinophilic infiltration of the tissues. T₂H cells secrete the cytokines IL-4 and IL-5, which are necessary for activation of mast cell and eosinophilic responses. In addition, these cytokines deactivate macrophages and promote the production of IgE and IgG antibodies by the B lymphocytes. Type IVd reactions are very rare and involve the recruitment and activation of neutrophils by T lymphocytes that specifically secrete IL-8. The only disorder of this subtype is acute generalized exanthematous pustulosis (AGEP), which presents with neutrophil-filled sterile pustules of the skin, fever, and massive leukocytosis.

Type IVc hypersensitivity reactions are cytotoxic responses mediated by CD4⁺ and CD8⁺ lymphocytes that secrete perforin and granzyme B. Cytotoxic lymphocytes (CTLs) bind antigen fragments that are displayed on MHC molecules found on the surface of APCs. Peptides derived from cytosolic antigens (e.g., viral) are presented by MHC class I molecules and activate CD8⁺ T cells, which kill any cell displaying the foreign antigen. Peptides derived from proteins degraded as a result of phagocytic ingestion (e.g., bacteria) are presented on MHC class II molecules, which activate CD4⁺ T cells. Once activated in this manner, CD4⁺ T cells can be considered cytotoxic because they are capable of activating other effector cells including cytotoxic CD8⁺, macrophages, and B lymphocytes.

In viral infections, cell damage is frequently the result of CTL responses rather than cytotoxic effects of the invading organism. While some viruses directly injure infected cells and are said to be cytopathic, other noncytopathic viruses do not. Because CTLs cannot distinguish between cytopathic and noncytopathic viruses, they destroy virtually all cells that are infected regardless of whether or not the virus is dangerous to the cell. In certain forms of hepatitis, for example, the destruction of liver cells is due to the host CTL response and not the virus.

**Allergic Contact Dermatitis**

Allergic contact dermatitis is a type IV hypersensitivity reaction associated with the activation of T₁H and T helper (17) lymphocytes. The inflammatory response takes place in two phases, sensitization and elicitation. It is usually confined to sites on the skin that have come in direct contact with a hapten (e.g., cosmetics, hair dyes, metals, topical drugs, plant oils). During the sensitization phase, hapten
Chapter 15  Disorders of the Immune Response

Hypersensitivity Pneumonitis

Hypersensitivity pneumonitis, also known as extrinsic allergic alveolitis, is a form of inflammatory lung disease that results from an exaggerated immune response after exposure to a multitude of inhaled organic particles or related occupational antigens. It was first described by Pepys et al. after exposure to moldy grains and hay and termed “farmer’s lung.” The offending agent was found to be Actinomyces, a bacterium commonly found in moldy foliage. The exact pathophysiologic mechanism of hypersensitivity pneumonitis remains unclear, but evidence supports a role for both type III and type IV immune responses. People demonstrate both high levels of antigen-specific serum IgG levels and combined cellular infiltration and granuloma formation. T, H cells appear to play a critical role in the development of the disease through the production and release of TNF, IFN-γ, IL-12, and IL-18 in lung tissue. Symptoms, including labored breathing, dry cough, chills and fever, headache, and malaise, usually begin several hours after exposure and subside within hours after the sensitizing antigens are removed. However, long-term sequelae have been reported.

Diagnosis of hypersensitivity pneumonitis is based upon a good history (occupational and otherwise) of exposure to possible antigens. CAT scans of the chest demonstrate areas of lobar vascularity and the presence of centrilobular nodules. Removal of the offending agent and oral corticosteroids are the only treatments available.

Latex Allergy

With the institution of universal precautions in the 1980s, the utilization of products containing natural rubber latex increased dramatically. Natural rubber latex is produced from the milky sap of the Hevea brasiliensis tree and at least 13 allergenic proteins have been isolated from it to date, any one of which can illicit an allergic response in susceptible people. In addition, it is a known component of over 40,000 products used in everyday life. As a result, latex allergy has emerged as a significant medical problem in westernized societies. At the peak of latex use in the mid- to late 1990s, 25% to 50% of people with spina bifida or genitourinary anomalies who underwent frequent surgical procedures and 17% of health care workers developed latex allergy as a result of chronic exposure.

While exposure to natural rubber latex is necessary for sensitization, other factors play a key role in the development of latex allergy. People with a history of atopic reactions, food allergies, and delayed hypersensitivity reactions are more likely to develop an allergic response to latex. The proteins found in latex are found in many naturally occurring substances including tree pollens, avocado, bananas, celery, and pears so cross-sensitivity is possible. Genetic polymorphisms in over 30 genes located on 15 different chromosomes have been implicated in the development of allergic reaction but have not yet been definitively identified for latex hypersensitivity.

Exposure to latex may occur by a variety of mechanisms including contact with skin and mucous membranes, inhalation, contact with internal tissues, or through intravascular injection. The most severe reactions have resulted from latex proteins coming in contact with the mucous membranes of the mouth, vagina, urethra, or rectum. Children with meningomyelocele and genitourinary anomalies (spina bifida) who undergo frequent examinations and treatments involving the mucosal surface of the bladder or rectum are at particular risk for development of latex allergy. Anaphylactic reactions have been caused by exposure of the internal organs to the surgeon’s gloves during surgery.

When natural rubber is processed in the manufacturing of latex-containing products, several accelerants, curing agents, antioxidants, and stabilizers are added to the liquid latex. Because any one of the substances with allergenic potential present in the final latex mixture is capable of triggering an allergic response, it can sometimes makes identification of the offending allergenic agent difficult. To further complicate the picture, when latex gloves are manufactured for use in health care, cornstarch powder is applied to the gloves so they can be more easily put on the hands. Unfortunately, the cornstarch glove powder plays an important role in the allergic response.
because latex proteins particles are readily absorbed by glove powder and can become aerosolized during the application and/or removal of the gloves, causing the development of symptoms in sensitized people. This is especially true in the operating room where high levels of aerosolized latex can be found.

Latex allergy can present as a type I IgE-mediated hypersensitivity reaction, type IV cell-mediated hypersensitivity reaction, or a combination of the two. Frequently, the exact pathophysiologic mechanism is unclear because the activation of the humoral and cell-mediated immune response are so intimately connected.

Type I, IgE-mediated hypersensitivity reactions develop in response to sensitization to one or more of the specific latex proteins. These reactions are immediate and often life threatening, occurring within minutes of exposure. Clinical manifestations range from mild to severe and include urticaria, wheezing, nasal congestion, coryza, rhinoconjunctivitis, bronchospasms, systemic hypotension, anaphylaxis, and cardiovascular collapse.

Type IV hypersensitivity reactions to latex gloves are the most common form of latex allergy seen. In this form of allergy, people usually develop a contact dermatitis to one of the chemical additives rather than the latex proteins within 48 to 96 hours of exposure. The contact dermatitis often affects the dorsum of the hands and is characterized by a vesicular, pruritic rash. When glove contact is continued, the area becomes crusted and thickened. Treatment is with topical corticosteroids during the acute phase and avoidance of all latex-containing products.

Diagnosis of latex allergy is based upon the person’s history and the presence of symptoms after exposure to latex-containing products. Since many of the reported reactions to latex gloves are the result of a nonimmunologic, irritant dermatitis, it is important to differentiate between nonallergic and allergic skin reactions. Definitive diagnosis is made through skin prick testing or intradermal injection of allergen and confirmed through latex-specific serum IgE immunoassays. In people with negative immunoassays, a contact test may be performed if the history is compelling as false negatives can occur. Regardless of the technique utilized, all equipment and drugs necessary to treat anaphylaxis must be readily available.

Treatment of latex allergy consists mainly of avoidance measures and requires a great deal of education directed toward the latex-sensitive person and his/her family. People with known latex allergy should avoid contact with any product suspected of containing latex until verified by the manufacturer. All surgical and medical procedures on people with latex allergy should be carried out in a latex-free environment. People with severe type I IgE-mediated hypersensitivity reactions should be instructed to obtain and wear a medic alert bracelet or necklace. Health care workers with severe and life-threatening allergy may be forced to change employment. If type I reactions occur, they are treated with epinephrine, antihistamines (H1 and H2 blockers), and systemic corticosteroids in order to maintain airway patency and restore hemodynamic stability.111

Hypersensitivity reactions are exaggerated immunologic responses to environmental, food, or drug antigens that would not affect most of the population. There are four basic categories of hypersensitivity responses: (1) type I responses, which are mediated by the IgE-class lgs and include anaphylactic shock, hay fever, and bronchial asthma; (2) type II responses, which involve complement-activated cell destruction (Rh incompatibility), ADCC, complement- and antibody-mediated inflammation (e.g., Goodpasture disease), and antibody-mediated cell dysfunction (e.g., Graves disease and myasthenia gravis); (3) type III, immune complex–mediated hypersensitivity disorders, which involve the formation and deposition of insoluble antigen–antibody complexes in blood vessels causing the development of vasculitis and organ damage as seen in SLE or acute glomerulonephritis, systemic immune complex disease (serum sickness), and local immune complex disease (Arthus reaction); and (4) type IV cell-mediated hypersensitivity reactions, which are subdivided into four different types based upon the T-cell population involved and the pathophysiologic response.

Latex allergy can involve a type I, IgE-mediated reaction or a type IV, cell-mediated response. The most common type of allergic response to latex is a contact dermatitis caused by a type IV, delayed-type hypersensitivity reaction to rubber additives. The less common, type I, IgE-mediated response is caused by sensitization to the latex protein and can precipitate far more serious anaphylactic reactions.

Traditionally, transplantation can be defined as the process of taking cells, tissues, or organs, called a graft, from one person and placing them into another person where they take over the normal function of the tissues replaced. Grafts transplanted from another person are known as allografts. In certain circumstances grafts are can be taken from one part of the body and transplanted in another part of the body in the same person. These grafts are referred to as autografts. The person who provided the graft is referred to as the donor, and the
person who receives the graft is called either the recipient or the host. Tissue transplantation has become routine because of improved medical technology, but serious complications still occur. The most important of which is graft rejection mediated by the host’s immune system.

In order for transplantation to be successful, it is essential for the host’s immune system to recognize the graft as “self” rather than “nonself.” It is the function of the T lymphocytes to respond to a limitless number of antigens, while at the same time ignoring self-antigens expressed on tissues. The MHC molecules or human leukocyte antigens (HLAs) expressed on the surface of cells enable the lymphocytes to do just this. Circulating B and T lymphocytes destroy cells that express unfamiliar peptide fragments on the MHC. Transplanted tissue can be categorized as an autologous graft (autograft) if donor and recipient are the same person, syngeneic graft if the donor and recipient are identical twins, and allogeneic (or allograft) if the donor and recipient are unrelated but share similar HLA tissue expression. The HLA molecules that are recognized as foreign on allografts are called alloantigens. Donors of solid organ transplants can be living or dead (cadaver) and related or nonrelated (heterologous). The likelihood of rejection varies indirectly with the degree of HLA similarity that exists between the donor and recipient.

Mechanisms Involved in Transplant Rejection

The process of transplant rejection involves a complex but coordinated cell-mediated and antibody-mediated immune response. While T lymphocytes have received the most attention as mediators of transplant rejection, it is now known that B cells, macrophages, eosinophils, and NK cells have a significant impact on the quality and quantity of the rejection process. In fact, when T cell–depleting regimens are significant impact on the quality and the quantity of the rejection process. B cells, macrophages, eosinophils, and NK cells have a significant impact on the quality and quantity of the rejection process. In fact, when T cell–depleting regimens are employed prior to transplantation, the importance of these cells in the rejection process becomes more evident. Three classic forms of rejection exist: cell mediated, antibody mediated, and chronic rejection, although a mixed pattern of rejection can occur as well.

The most common form of acute allograft rejection is T cell-mediated and known as cellular rejection. It is initiated by the presentation of donor alloantigens to host T lymphocytes by antigen-presenting dendritic cells and macrophages. APCs may come from recipient or donor tissue. When the APCs are donor in origin, T lymphocyte activation is said to occur via the direct pathway. When the APCs are the recipient’s innate cells, T-lymphocyte activation is said to be via the indirect pathway, which resembles the pathway normally involved in the recognition of foreign substances. Most of the alloantigen is presented in association with MHC I or II molecules, resulting in destruction of graft cells by CD8+ cytotoxic T cells or the initiation of a delayed hypersensitivity reactions triggered by CD4+ helper T cells.

T cells of the recipient recognize allogeneic MHC molecules on the surface of APCs that have migrated to lymphoid tissue and on the graft itself. CD8+ cells recognize class I MHC molecules and differentiate into mature CTLs, which directly kill the graft tissue as they would any foreign substance. CD4+ helper T cells recognize class II MHC molecules and differentiate into T-helper effector cells, which secrete cytokines that influence almost all other cells of the immune response including B lymphocytes, cytotoxic T cells (CD8+), macrophages, and NK cells. In addition, the cytokines cause increased vascular permeability and local accumulation and activation of macrophages, and eventual graft injury. While it was traditionally believed that T,H helper cells mediated rejection and T,H cells promoted tolerance, it is now known that T,H helper cells alone can be responsible for graft rejection mediated via eosinophil activation.

Antibody-mediated or humoral rejection is caused by B-lymphocyte proliferation and differentiation into plasma cells that produce donor-specific antibodies (DSAs). These antibodies may be preformed if the immune system was exposed pretransplantation, or they may be produced de novo following transplantation. B lymphocytes also play an antibody-independent role in graft rejection through the secretion of proinflammatory cytokines and chemokines and the participation in antigen presentation. Antibody-mediated rejection can be hyperacute or acute in origin. Hyperacute rejection occurs almost immediately after vascular reperfusion to graft tissue occurs. Preformed antibodies against HLA antigens are deposited in the tissue endothelium and microvasculature where they activate the classic complement pathway causing tissue necrosis and graft injury. Hyperacute rejection is considered a type III hypersensitivity response. Acute antibody-mediated rejection occurs within days to weeks after transplantation. The time frame is dependent upon whether or not the recipient received immunosuppressive therapy prior to transplantation. Previous exposure to the relevant HLA antigens is responsible, but unlike in hyperacute rejection, high circulating antibodies are not present at the time of transplantation. Over a period of several days, high titers of complement-fixing antibodies are generated, which cause injury by several mechanisms, including complement-dependent cytotoxicity, inflammation, and antibody-dependent cell-mediated cytotoxicity. Regardless of the mechanism, the initial target of these antibodies in rejection appears to be the graft vasculature.

Chronic rejection involves immune-mediated inflammatory injury to a graft that occurs over a prolonged period. It is most often due to the inability to maintain adequate immunosuppression necessary to control residual circulating antigraft T lymphocytes or antibodies. Chronic rejection manifests itself with a progressive decline in tissue function usually as a result of vascular injury and impaired blood supply. T lymphocytes and macrophages infiltrate the graft and set up a chronic immune response that causes cellular hypertrophy and subendothelial thickening. Antibody-mediated rejection may be responsible for chronic rejection in patients with undetected low levels of preexisting or de novo DSAs. In renal transplantation, it is characterized by a gradual rise in serum creatinine over a period of 4 to 6 months.
Graft Versus Host Disease

GVHD is a major complication that most frequently occurs after allogeneic stem cell transplantation. There are three fundamental requirements for the development of GVHD:

1. The graft must contain cells that are immunologically competent.
2. The recipient’s cells must express antigens that are not present on donor cells.
3. The recipient must be immunologically compromised and incapable of mounting an effective immune response.117,118

Cases of GVHD have also been reported in other settings where tissues containing T lymphocytes, such as blood products, bone marrow, or solid organs (liver), are transplanted into people who are immunocompromised.119

GVHD occurs when donor T cells react to HLAs present on host cells. The incidence of acute GVHD directly correlates with the degree of mismatching between recipient and host HLA proteins. Class I HLA (A, B, and C) proteins are expressed on most nucleated cells in the body. Class II HLA proteins (DR, DQ, and DP) are mainly expressed on hemopoietic cells including B lymphocytes, dendritic cells, and monocytes. Class II HLA protein expression can also be stimulated on other cell types during inflammation and tissue injury.117 Therefore, donors and recipients are matched for class I HLA (A, B, and C) and class II CRB1 antigens in order to decrease the chance of rejection. However, even with tissue matching, 40% of HLA-identical graft recipients develop signs of system GVHD requiring treatment with high-dose steroids. It is believed that GVHD is the result of genetic differences encoded that encode for minor histocompatibility proteins.119

The development of GVHD involves a three-step process: (1) activation of recipient APCs; (2) activation, proliferation, differentiation, and migration of donor T lymphocytes; and (3) target tissue destruction.117 Prior to transplantation, host APCs are in a state of heightened activation as a result of the underlying disease process and hemopoietic stem cell transplantation (HSCT) preconditioning regimens. As a result, these cells exhibit amplified expression of adhesions molecules, MHC antigens, and costimulatory molecules. Following transplantation, donor T lymphocytes come in contact with these “heightened” APCs and activate both CD4+ and CD8+ T cells. The end result is the stimulation of a complex cascade of cellular mediators and soluble inflammatory agents that amplify tissue injury and promote tissue destruction.

GVHD can be acute or chronic. Acute GVHD usually develops within the first 100 days of transplantation, whereas chronic GVHD occurs sometime after that. However, cases of late-onset acute GVHD have been reported, and in some cases, patients present with features of both.120 Signs and symptoms usually develop first in the skin, coinciding with the engraftment of donor cells. People present with a pruritic, maculopapular rash that starts on the hands and feet but ultimately extends over the entire body. In severe cases, the skin can blister and ulcerations may develop. Gastrointestinal symptoms include nausea, anorexia, diarrhea, and abdominal pain. Gastrointestinal bleeding is an ominous sign as it indicates mucosal ulceration. Liver disease is common but is frequently hard to differentiate from liver involvement normally seen after transplantation. It can progress to the development of venoocclusive disease, drug toxicity, viral infection, iron overload, extrahepatic biliary obstruction, sepsis, and coma.120

The severity of acute GVHD is determined based upon the involvement of the three primary target organs affected (skin, GI tract, and liver). Severe GVHD is associated with a poor prognosis and a long-term survival rate of 5%.

Chronic GVHD is a major late cause of death after HDCT. GVHD can progress to the acute form of the disease, recur some time after resolution of an acute process, or develop de novo. The greatest risk factors for the development of chronic GVHD are advanced recipient age and a previous history acute GVHD. Signs and symptoms of chronic GVHD are typical of an autoimmune process and can affect all major organ systems within the body.

Prevention of GVHD focuses on regimens that specifically deplete donor T lymphocytes, but have been met with mixed long-term success. Regimens including the removal of T cells from donor graft prior to transplantation and the administration of antibodies against T cells in vivo have been studied extensively but are associated with high rates of graft failure. Immunosuppressive or anti-inflammatory drugs such as cyclosporine and tacrolimus or glucocorticoids can be used to block T-cell activation and the action of cytokines.

IN SUMMARY

Transplantation can be defined as the process of taking cells, tissues, or organs, called a graft, from one person and placing them into another person where they take over the normal function of the tissues replaced. While advances in medicine had dramatically improved the long-term survival following transplantation, rejection still exists as a major barrier to success. Rejection is the process by which the recipient’s immune system recognizes the graft as foreign, mounts an immunologic response, and destroys it. Destruction of the cells or tissues of the graft can be cell mediated, antibody mediated, or a combination of both processes. Hyperacute antibody rejection occurs almost immediately after transplantation and is caused by existing recipient antibodies to graft antigens that initiate an immediate hypersensitivity reaction in the blood vessels of the graft. Acute antibody-mediated rejection occurs within days to weeks after transplantation. Previous exposure to the relevant HLA antigens is responsible, but unlike in hyperacute rejection, high circulating antibodies are not present at the time of transplantation. Chronic rejection occurs over a prolonged period and is caused by T cell–generated cytokines that stimulate fibrosis of graft tissue.

GVHD occurs when immunologically competent donor cells or are transplanted into recipients who are
immunologically compromised. Three basic requirements are necessary for GVHD to develop: (1) the donor cells must be immunologically competent, (2) the recipient tissue must bear antigens foreign to the donor cells, and (3) recipient must be immunologically compromised so that it cannot destroy the transplanted cells.

**AUTOIMMUNE DISEASE**

After completing this section of the chapter, you should be able to meet the following objectives:

- Discuss the mechanisms of self-tolerance as they relate to the development of autoimmune disease.
- Discuss the possible mechanisms underlying autoimmune disease.
- Describe the criteria for establishing an autoimmune basis for a disease.

Autoimmune diseases are a heterogeneous group of disorders that occur when the body’s immune system fails to differentiate “self” from “nonself” and mounts an immunologic response against host tissues. Autoimmune diseases can affect almost any cell type, tissue, or organ system. Some autoimmune disorders, such as Hashimoto thyroiditis, are tissue specific. Others, such as SLE, are systemic, affecting multiple organs and systems. Chart 15.2 lists some of the more common autoimmune diseases.

**Immunologic Tolerance**

A key feature of the immune system is its ability to differentiate between foreign antigens and self-antigens. The capacity of the immune system to differentiate self from nonself is called self-tolerance. The development of self-tolerance relies upon two coordinated processes: central tolerance, the elimination of autoreactive lymphocytes during maturation in the central lymphoid tissues, and peripheral tolerance, the functional suppression of autoreactive lymphocytes in peripheral tissues that have escaped destruction in the thymus.121 Autoreactivity is the process by which an organism acts against its own tissue.

Activation of the immune system requires presentation of foreign antigens to the immunologically active B and T cells. Antigen expression is encoded on the MHC genes, which determine the specific HLA antigens present on cell surfaces. During T-cell development in the thymus, T lymphocytes (prolymphocytes) undergo random rearrangement of specific gene loci responsible for the coding of antigen receptors. The prolymphocytes with TCRs that appropriately bind to MHC are positively selected for, while prolymphocytes with high affinity for self-antigen or autoreactivity are destroyed.121 Similar processes take place in the elimination of B lymphocytes that have high affinity for autoantigens.122 The main objective is to produce a population of B and T lymphocytes that are immunologically unresponsive in the presence of self-antigens prior to their release into the central circulation. Anergy is the complete loss of lymphocyte response to an antigen and can result in a diminished or absent cellular and/or humoral immunologic response.

**B-Cell Tolerance**

Under normal circumstances, circulating B lymphocytes do not produce antibodies against host tissues. B-cell antibody production is normally kept in check by the help of CD4+ T-helper cells. In addition, autoreactive B lymphocytes can be eliminated by apoptosis in the central lymphoid tissues, spleen, and peripheral lymph nodes, or they can be functionally inactivated in a process known as anergy. However, in many autoimmune diseases, the immune system loses its ability to recognize self and produces antibodies, also known as autoantibodies, against host tissues. For example, in Graves disease, hyperthyroidism is the result of autoantibody-induced hyperactivity of the TSH receptor (see Fig. 15.3).

**T-Cell Tolerance**

The primary mechanisms of T cell tolerance involve a process of positive and negative selection of maturing lymphocytes (Fig. 15.6). When immature lymphocytes migrate into the thymus, the T-cell lineage undergoes TCR gene rearrangement at the \( \alpha \) and \( \beta \) loci.\(^{121}\) At this point, they can mature into either CD4\(^+\) or CD8\(^+\) cells and are considered to be double positive (CD4\(^+/\)8\(^-\)). After rearrangement, T cells with TCRs that respond appropriately to self-peptide–MHC complexes and possess little avidity for the antigen are signaled by the release of cytokines and chemokines to migrate into the thymic medulla and mature into CD4\(^+/\)8\(^-\) and CD4\(^-/\)8\(^+\) or single-positive lymphocytes.\(^{123,124}\) This is known as positive selection. In contrast, T cells with TCRs that possess high avidity for the self-peptide–MHC complex are directed to undergo apoptosis or programmed cell death.\(^{125}\) This is known as clonal deletion or negative selection and takes place in the thymic medulla as well. While the processes governing the selection and maturation of T lymphocytes are extensive, autoreactive T cells can escape into the periphery, where peripheral mechanisms for the development of self-tolerance become important.

Several peripheral mechanisms are available to deal with autoreactive cells that escape central selection. One primary mechanism begins with the development of a specialized subpopulation of T lymphocytes. CD4\(^+\)CD25\(^+\) regulator T cells are a subset of T lymphocytes produced in the thymus that regulate antigen-specific tolerance. These regulator T cells target and abolish the response of autoreactive T cells that have been released into the peripheral circulation by interrupting the production and release of IL-2.\(^{121}\) Regulatory T cells are also capable of inducing tolerance to foreign antigens by inhibiting activation and proliferation of naive CD4\(^+\) T cells in response to antigen.\(^{121,126}\)

The activity of autoreactive T cells can also be inhibited by local anatomic and physiologic factors. Some T cells are
located in areas of the body where they fail to come in contact with their corresponding antigens (e.g., blood–brain barrier), so they remain immunologically inactive. In other cases, autoreactive T cells encounter their corresponding antigens, but the costimulatory factors necessary for their activation are missing. The peripheral activation of T cells requires presentation of a peptide antigen in association with MHC molecules on the APCs as well as a set of secondary costimulatory factors. Because costimulatory signals are not strongly expressed on most normal tissues, the encounter of the autoreactive T cells with their specific target antigens fails to initiate an immunologic response resulting in the development of anergy.

Another mechanism essential for the maintenance of functional tolerance involves the apoptotic death of autoreactive T cells when excessive or repeated TCR activation has occurred. This process is referred to as activation-induced cell death (AICD).127 AICD is necessary in order to prevent activated T cells from inducing an autoimmune response. It is a normal process of the immune system designed to maintain internal homeostasis. AICD is mediated by the interaction between an apoptotic cell surface receptor (called FAS) that is present on the T cell and a soluble membrane messenger molecule known as the FAS ligand. The FAS/FAS ligand bound activates the intracellular processes that result in programmed cell death. The expression of the FAS receptor is markedly increased on the cell surfaces of activated T cells. Therefore, expression of the FAS messenger molecule by the same cohort of activated autoreactive T cells can result in removal of the population from the circulation.

**KEY POINTS**

**IMMUNOLOGIC TOLERANCE**

- Immunologic self-tolerance is the ability of the immune system to distinguish between self and nonself antigens. It is mediated through central and peripheral mechanisms that delete autoreactive immune cells or render them unresponsive to autoantigen.
- The development of self-tolerance relies upon two coordinated processes: central tolerance, the elimination of autoreactive lymphocytes during maturation in the central lymphoid tissues, and peripheral tolerance, the functional suppression of autoreactive lymphocytes in peripheral tissues that have escaped destruction in the thymus.

**Mechanisms of Autoimmune Disease**

While it is clear that autoimmune disease results from a loss of self-tolerance, the exact mechanisms are largely unknown. Autoimmune diseases are a heterogeneous group of disorders, so a combination of both genetic and environmental factors plays a significant role. Gender may also be a factor since many autoimmune disorders such as SLE are predominantly seen in women, suggesting that female hormones like estrogens may play a role in the development of certain autoimmune diseases. Estrogen has been shown to have strong immunomodulatory effects including the stimulation of autoreactive B-lymphocyte antibody production, increased leukocyte adhesion to endothelial cells, and increased cytokine production.128

**Heredity**

While the pathophysiology of autoimmune disease is complex involving both environmental and genetic influences, it is known that heredity has a significant impact on the prevalence of these disorders. Autoimmune disorders are not inherited in the traditional fashion such as with a single gene mutation. Rather, people with autoimmune disorders exhibit susceptibility genes that act in concert with environmental factors to increase a person’s risk of developing the disease process.129 In addition, many of these genes are shared between autoimmune disorders with similar underlying features. For example, type I IFN is a central mediator of the innate immune response stimulating monocyte maturation, plasma cell maturation and Ig class switching, and cytotoxic T-cell activity. Patients with SLE or systemic sclerosis (SSc) demonstrate defects in the IFN regulatory factor 5 (IRF5) gene, resulting in the abnormal transcription of IFN.129 In other cases, heritable changes occur as a result of changes in gene expression, rather changes in DNA sequencing. This is termed epigenetics. This is the result of the methylation of deoxycytosine (dC) bases in cytosine–guanine DNA base pairs.130 As a result, the chromatin structure is altered in such a way that it cannot be accessed during the normal processes of DNA transcription and the functions encoded in the DNA sequence cease.

The high concordance rates in first-degree relatives and monozygotic twins provide strong evidence for the role of inheritance in autoimmune disorders. First-degree relatives have a relative risk of rheumatoid arthritis that is two to four times that of the general population.131,132 Studies of monozygotic and dizygotic twins indicate that rheumatoid arthritis is approximately 65% heritable with many affected people sharing alleles for the same anticyclic citrullinated peptide (anti-CCP) antibody.131 It is clear that autoimmunity does not develop in all people with genetic predisposition. Therefore, other factors known as “triggering events” interact to precipitate the altered immune state. In most cases the event or events that trigger the development of an autoimmune response are unknown, but in many cases it appears that the “trigger” may be a viral infection, a chemical substance, or a self-antigen from a body tissue that has been hidden from the immune system during development and is suddenly expressed.

**Environmental Factors**

The role of environment in the development of autoimmune disease is complex. The incidence of some autoimmune diseases, such as type I diabetes mellitus, has increased...
in recent years faster than would be expected based upon genetic mechanisms alone, suggesting an increased impact of environmental factors in genetically susceptible people.\(^{133}\) Environmental factors including viral infection, lack of exposure to maternal antibodies through breast-feeding, maternal smoking, and exposure to hazardous chemicals appear to be involved in the pathogenesis of autoimmune disorders, but their precise role in initiating the autoreactive response is largely unknown. Various factors work in concert resulting in the loss of self-tolerance including breakdown of T-cell anergy, release of sequestered antigens, molecular mimicry, and the development of superantigens.

**Breakdown in T-Cell Anergy.** Anergy is a state of reduced function, in which an immunocompetent, antigen-specific T cell is unable to respond to an appropriate stimulus.\(^ {134}\) Anergy can develop if there is loss of normal costimulatory factors in the face of normal T-cell activation or from altered/chronic TCR stimulation. Primary CD4\(^ +\) and CD8\(^ +\) T cells' anergy is characterized by defective production of IFN-\(\gamma\) and TNF-\(\alpha\).\(^ {134}\) In addition, regulatory T cells control T-cell activation by failing to express T-cell stimulating inflammatory cytokines. Most normal tissues do not express costimulatory molecules and as a result are protected from circulating autoreactive T cells. However, if normal cells are induced to express costimulatory factors, then normal anergy is inhibited and autoimmunity can develop. This can occur after an infection or in situations where there is tissue necrosis and local inflammation.

**Release of Sequestered Antigens.** Under normal circumstances, the body does not produce antibodies against self-antigens. If self-antigens have been completely sequestered during T-cell development and reintroduced into the immune system, they are likely to be treated as foreign antigens. This has been documented in cases of posttraumatic uveitis and orchiditis after systemic release of spermatozoa and ocular antigens. Other times self-antigens may change their structure and, once they come in contact with T cells, are no longer recognized as innate to the host. Once an autoimmune process has been initiated, it tends to be become amplified and progress, sometimes with sporadic relapses and remissions. This occurs because the initial inflammatory process releases these altered self-antigens where they come in contact with the cells of the immune system. The result is continued activation of new lymphocytes that recognize the previously hidden epitopes.

**Molecular Mimicry.** It is known that viral infections can serve as triggers in many autoimmune processes, but the mechanism by which this occurs is not completely understood. *Molecular mimicry* is one theory that has been postulated to describe the mechanisms by which infectious agents or other foreign substances trigger an immune response against autoantigens. If a susceptible host is exposed to a foreign antigen that is immunologically similar to its own autoantigens (share epitopes), but which differs sufficiently to trigger an immune response, cross-reactivity between the two antigens and damage to host tissues can occur.\(^ {135}\)

Molecular mimicry has been used to explain the cardiac damage associated with acute rheumatic fever after infection with group A beta-hemolytic streptococci and the demyelinating injury in multiple sclerosis.\(^ {135}\) People with rheumatic fever have high levels of circulating antibodies against the type 5 streptococcal M protein, an antigen found in the microbial cell membrane and which demonstrates cross-reactivity with cardiac myosin. Multiple viruses that are destroyed by cytotoxic T cells (CD8\(^ +\)) share common epitopes with the myelin basic proteins targeted in people with multiple sclerosis. However, not everyone exposed to these organisms goes on to develop autoimmunity. This may be due to differences in HLA expression. The HLA type expressed by the cell determines exactly which fragments of a pathogen are displayed on the surface of the APCs for presentation to T cells. Some fragments may be cross-reactive and others may not. In the spondyloarthropathies B-lymphocyte cross-reactivity exists between gram-negative bacterial membrane peptides, and specific host HLA-B27 antigens have been implicated in the development of the disease.\(^ {135,136}\)

**Superantigens.** Superantigens are a family of related substances, including staphylococcal and streptococcal exotoxins, that induce uncontrolled proliferation and activation of T lymphocytes, causing fever, shock, and death. Unlike antigens, superantigens bind as intact molecules to a wide variety of class II MHC molecules on APCs and then to the TCR on the variable region of the \(\beta\)-chain (TCR V\(\beta\)).\(^ {137}\) Every superantigen is capable of binding a large subset of TCR V\(\beta\) domains and as a result activating up to 20% of all T cells.\(^ {137}\) This can be as high as 20% compared with only 1 in 10\(^5\) to 10\(^6\) naive T cells that are responsive to conventional peptide antigen. Superantigens are involved in several diseases, including food poisoning and toxic shock syndrome.

**Diagnosis and Treatment of Autoimmune Disease**

The diagnosis of autoimmune disorders is not always easy. There are over 80 identified autoimmune disorders, and many have overlapping presentations. In addition, many of the manifestations are nonspecific and are frequently seen in other disease processes that do not of autoimmune etiology. Diagnosis is therefore made based upon evidence of autoimmunity as indicated by history as well as physical and serological findings. Each autoimmune disease is associated with certain clinical signs and laboratory findings that practitioners screen for during the diagnostic workup. Because the etiology of autoimmunity is multifactorial, it is unlikely that any one specific genetic testing alone will be able to determine a diagnosis with 100% certainty.

The basis for most serologic assays is the demonstration of antibodies directed against tissue antigens or cellular components. The results of serologic testing are correlated
with the physical findings during the diagnostic workup. For example, a child who presents with a chronic or acute history of fever, arthritis, and a macular rash and has high levels of antinuclear antibody has a probable diagnosis of SLE. The detection of autoantibodies in the laboratory is usually accomplished by one of three methods: indirect fluorescent antibody (IFA) assays, enzyme-linked immunosorbent assay (ELISA), or particle agglutination of some kind. Each technique relies upon the specificity of antibody for antigen. In the ELISA and IFA, the person’s serum is diluted and allowed to react with an antigen coated surface (i.e., whole, fixed cells for the detection of antinuclear antibodies) so that the antibody present in the sample can bind the antigen. The serum antibody is then linked to an enzyme or secondary antibody producing a visible reaction that allows the amount of antibody present to be quantified. Particle agglutination assays are much simpler because the binding of the person’s antibody to antigen-coated particles causes a visible agglutination reaction, and a secondary reaction is not required.

Treatment of autoimmune disorders is dependent upon the magnitude of the presenting manifestations and underlying mechanisms of the disease process. Since in many cases the pathophysiologic mechanisms are not always known, treatment may be purely symptomatic. Corticosteroids and immunosuppressive drugs are the mainstay of therapy directed at arresting or reversing the cellular damage caused by the autoimmune response. Plasmapheresis has been utilized in severe cases to remove autoreactive cells from the circulation.

Recent therapies for the treatment of autoimmune disorders have focused on targeting the specific lymphocytes and cytokines involved in the autoimmune response. For example, type I interferons (IFNα) have been implicated in the development of many autoimmune processes including SLE. Anti-IFN monoclonal antibody therapy has been shown to inhibit the overexpression of IFN genes and suppress the expression of interferon-dependent cytokines (e.g., TNF α, IL-10, and IL-1).\textsuperscript{138,139} Other recent therapies deplete autoreactive B cells by targeting CD20 (rituximab), modulate B-cell activity without depleting the lymphocyte lineage (epratuzumab), block B cell growth factors (belimumab), or inhibit the communication between T and B cells by blockade of costimulatory factors (CTLA-4 Ig).\textsuperscript{138} Unfortunately, the success of these treatments has been variable.

**IN SUMMARY**

Autoimmune disorders are caused by a loss of immunologic self-tolerance, which results in damage to body tissues. Autoimmune diseases are a heterogeneous group of disorders and depending upon the target of the autoreactive lymphocytes can affect almost any cell or tissue of the body. The ability of the immune system to differentiate self from nonself is called self-tolerance and is normally maintained through central mechanisms that delete autoreactive lymphocytes before they come in contact with an autoantigen. Cells that escape deletion by central mechanisms may be suppressed or inactivated in the periphery. Defects in any of these mechanisms can be responsible for the development of autoimmune diseases.

T-cell activity is modulated through the expression of the HLA–MHC complex on cellular surfaces. Antigens are normally presented to TCRs in combination with MHC molecules. This interaction activates a variety of immune processes that culminate in destruction of the “foreign antigen.” Disruption of any step in the antigen recognition process can result in the loss of self-tolerance including breakdown of T-cell anergy, release of sequestered antigens, molecular mimicry, and the development of superantigens. Diagnosis of autoimmune disease is made based upon evidence of autoimmunity as indicated by history as well as physical and serological findings.

**REVIEW EXERCISES**

1. A 20-year-old woman has been diagnosed with IgA deficiency. She has been plagued with frequent bouts of bronchitis and sinus infections.
   A. Why are these types of infections particularly prominent in people with an IgA deficiency?
   B. She has been told that she needs to be aware that she could have a severe reaction when given unwashed blood transfusions. Explain.

2. People with impaired cellular immunity may not respond to the tuberculin test, even when infected with *Mycobacterium tuberculosis*.
   A. Explain.

3. A 32-year-old man presents in the allergy clinic with complaints of allergic rhinitis or hay fever. His major complaints are those of nasal pruritus (itching), nasal congestion with profuse watery drainage, sneezing, and eye irritation. The physical examination reveals edematous and inflamed nasal mucosa and redness of the ocular conjunctiva. He relates that this happens every fall during “ragweed season.”
   A. Explain the immunologic mechanisms that are responsible for this man’s symptoms.
   B. What type of diagnostic test might be used?
   C. What type of treatment(s) might be used to relieve his symptoms?

4. People with intestinal parasites and those with allergies may both have elevated levels of eosinophils in their blood.
   A. Explain.
References

The acquired immunodeficiency syndrome (AIDS) is a disease caused by infection with the human immunodeficiency virus (HIV) and is characterized by profound immunosuppression with associated opportunistic infections, malignancies, wasting, and central nervous system (CNS) degeneration. AIDS is considered a chronic illness today.

As a national and global problem, the degree of morbidity and mortality caused by HIV, as well as its impact on health care resources and the economy, is tremendous and unrelenting. At the end of 2010, it was estimated that there were nearly 34 million people worldwide living with HIV/AIDS.\(^1\) UNAIDS surveillance reports that new infections of HIV have decreased since 1997 by 27\% and that AIDS-related deaths have decreased by 21\% since 1995.\(^1\) Because the reporting of cases is not uniform throughout the world, many countries may not be accurately represented in this number. Most of the new infections worldwide are in people younger than 25 years of age who live in developing countries.

In the United States, 1,178,350 people were living with HIV by the end of 2008.\(^2\) Each year the Centers for Disease Control and Prevention (CDC) tracks HIV/AIDS incidence. In 2009, there were approximately 48,000 new cases of HIV in people.\(^3\) The CDC determined that 61\% of these new cases occurred in gay and bisexual men with Black/African
American ethnicity who have a seven times higher incidence of acquiring HIV compared to white gay and bisexual men. Approximately 31,872 of the yearly new cases are men, 9973 are women, and children less than 13 years constituted 166 cases in 2009.

**Emergence of AIDS**

Compared with other human pathogens, HIV evolved fairly recently. In 1981, clinicians in New York, San Francisco, and Los Angeles recognized a new immunodeficiency syndrome in homosexual men. Initially, the syndrome was called GRID, for “gay-related immunodeficiency syndrome.” By the end of 1981, there had been several hundred cases reported, and the name was changed to **acquired immunodeficiency syndrome**, or AIDS. It soon became apparent that this disease was not confined to one segment of the population but was also occurring in intravenous drug users, people with hemophilia, blood transfusion recipients, infants born to infected mothers, and high-risk heterosexuals. Studies of these diverse groups led to the conclusion that AIDS was an infectious disease spread by blood, sexual contact, and perinatal transmission from mother to child.

An understanding of the virology of AIDS progressed with amazing efficiency. Within 3 years of the first cases being recognized, the virus that causes AIDS had been identified. The virus was initially known by various names, including human T-cell lymphotropic virus type 3 (HTLV-III), lymphadenopathy-associated virus (LAV), and AIDS-associated retrovirus (ARV). In 1986, the name **human immunodeficiency virus** became internationally accepted. The CDC Web site defines HIV and AIDS according to the 2009 CDC case definitions and multiple other surveillance data, including the transmission categories.

**KEY POINTS**

**THE AIDS EPIDEMIC AND TRANSMISSION OF HIV**

- AIDS is caused by the HIV.
- HIV is transmitted through blood, semen, vaginal fluids, and breast milk.
- People with HIV infection are infectious even when asymptomatic.

**Transmission of HIV Infection**

HIV is a retrovirus that selectively attacks the CD4+ T lymphocytes, the immune cells responsible for orchestrating and coordinating the immune response to infection. As a consequence, people with HIV infection have a deteriorating immune system and thus are more susceptible to severe infections with ordinarily harmless organisms. The virus responsible for most HIV infection worldwide is called **HIV type 1** (HIV-1). A second type, **HIV type 2** (HIV-2), is endemic in many countries in West Africa but is rarely seen in other parts of the world. The majority of people with HIV-2 (81%) are people who were born in West Africa. People with HIV-2 tend not to develop AIDS. The Bio-Rad Multispot HIV-1/HIV-2 Rapid Test is the most accurate and FDA-approved diagnostic test used to differentiate the two types of the HIV virus.

HIV is transmitted from one person to another through sexual contact, blood-to-blood contact, or perinatally. The CDC transmission categories of HIV for children include perinatal and other. The adult categories include male-to-male sexual contact, intravenous drug use, male-to-male sexual contact and intravenous drug use, heterosexual contact, and other.

Several studies involving more than 1000 uninfected, nonsexual household contacts with persons with HIV infection (including siblings, parents, and children) have shown no evidence of casual transmission. Transmission can occur when infected blood, semen, or vaginal secretions from one person are deposited onto a mucous membrane or into the bloodstream of another person.

Sexual contact is the most frequent mode of HIV transmission. HIV is present in semen and vaginal fluids. There is a risk of transmitting HIV when these fluids come in contact with a part of the body that lets them enter the bloodstream. This includes the vaginal and anal mucosa, superficial laceration, wounds, or sores on the skin. Contact with semen occurs during vaginal and anal sexual intercourse, oral sex, and donor insemination. Exposure to vaginal or cervical secretions occurs during vaginal intercourse and oral sex. In most cities in the United States, sexual transmission of HIV is primarily related to vaginal or anal intercourse. However, use of condoms is highly effective in preventing the transmission of HIV.

Because HIV is found in blood, the use of needles, syringes, and other drug injection paraphernalia is a direct route of transmission. Of the reported cases of AIDS in the United States, approximately 25% occurred among people who injected drugs. Transfusions of whole blood, plasma, platelets, or blood cells before 1985 resulted in the transmission of HIV. Seventy to eighty percent of people with hemophilia who were treated with factor VIII supplements before 1985 became infected with HIV. Since 1985, all blood donations in the United States have been screened for HIV, so there is no longer a transmission risk. Other blood products, such as gamma globulin or hepatitis B immune globulin, have not been implicated in the transmission of HIV.

Transmission from mother to infant is the most common way that children become infected with HIV. HIV may be transmitted from infected women to their offspring in utero, during labor and delivery, or through breast-feeding. Ninety percent of infected children acquired the virus from their mother. However, evidence suggests that if mother and infant are treated with one or two additional antiretroviral
medications along with zidovudine (standard practice is to administer zidovudine only), a statistically significant decrease in transmission of HIV occurs.  

Occupational HIV infection among health care workers is uncommon. Through December 2001, the CDC had received only 57 documented occupational HIV infections in the United States with no other cases submitted.8 Universal Blood and Body Fluid Precautions should be used in encounters with all people in the health care setting since it should be assumed that any person may have a transmissible infection.9 Occupational risk of infection for health care workers most often is associated with percutaneous inoculation (i.e., needle stick) of blood from a person with HIV infection. Transmission is associated with the size of the needle, amount of blood present, depth of the injury, type of fluid contamination, stage of illness of the person, and viral load of the person.

People with other sexually transmitted diseases (STDs) are at increased risk for HIV infection. The risk of HIV transmission is increased in the presence of genital ulcerative STDs (i.e., syphilis, herpes simplex virus infection, and chancroid) and nonulcerative STDs (i.e., gonorrhea, chlamydial infection, and trichomoniasis). HIV increases the duration and recurrence of STD lesions, treatment failures, and atypical presentation of genital ulcerative diseases because of the suppression of the immune system.

The HIV-infected person is infectious even when no symptoms are present. The point at which an infected person converts from being negative for the presence of HIV antibodies in the blood to being positive is called seroconversion. Seroconversion typically occurs within 1 to 3 months after exposure to HIV but can take up to 6 months.10–12 The time after infection and before seroconversion is known as the window period. During the window period, a person’s HIV antibody test result will be negative. Rarely, infection can occur from transfused blood that was screened for HIV antibody and found negative because the donor was recently infected and still in the window period. Consequently, the U.S. FDA requires blood collection centers to screen potential donors through interviews designed to identify behaviors known to present a risk for HIV infection.

Transmission occurs when the infected blood, semen, or vaginal secretions from one person are deposited onto a mucous membrane or into the bloodstream of another person. The primary routes of transmission are through sexual intercourse, through intravenous drug use, and from mother to infant. Blood transfusions and other blood products continue to be routes of transmission in some underdeveloped countries. Occupational exposure in health care settings accounts for only a tiny percentage of HIV transmission. HIV infection is not transmitted through casual contact or by insect vectors. There is growing evidence of an association between HIV infection and other STDs. Infected individuals can transmit the virus to others before their own infections can be detected by antibody tests.

PATHOPHYSIOLOGY AND CLINICAL COURSE

After completing this section of the chapter, you should be able to meet the following objectives:

- Describe the structure of HIV and trace its entry and steps in replication within the CD4+ T lymphocyte.
- Describe the alterations in immune function that occur in persons with AIDS.
- Relate the altered immune function in persons with HIV infection and AIDS to the development of opportunistic infections, malignant tumors, nervous system manifestations, the wasting syndrome, and metabolic disorders.

Molecular and Biologic Features of HIV

HIV-1 is an enveloped member of the retroviruses specifically the subfamily of lentiviruses.13 They can all produce slowly progressive fatal diseases that include wasting syndromes and CNS degeneration. Two genetically different but antigenically related forms of HIV, HIV-1 and HIV-2, have been isolated in people with AIDS. HIV-1 is the type most associated with AIDS in the United States, Europe, and Central Africa, whereas HIV-2 causes a similar disease principally in West Africa. HIV-2 appears to be transmitted in the same manner as HIV-1; it can also cause immunodeficiency as evidenced by a reduction in the number of CD4+ T cells and the development of AIDS. Although the spectrum of disease for HIV-2 is similar to that of HIV-1, it spreads more slowly and causes disease more slowly than HIV-1. Specific tests are now available for HIV-2, and blood collected for transfusion is routinely screened for HIV-2. Because most people with HIV have HIV-1, the discussion focuses on HIV-1.

HIV infects a limited number of cell types in the body, including a subset of lymphocytes called CD4+ T lymphocytes (also known as T-helper cells or CD4+ T cells), macrophages,
and dendritic cells. The CD4+ T cells are necessary for normal immune function. Among other functions, the CD4+ T cell recognizes foreign antigens and helps activate antibody-producing B lymphocytes. The CD4+ T cells also orchestrate cell-mediated immunity, in which cytotoxic CD8+ T cells and natural killer (NK) cells directly destroy virus-infected cells, tubercle bacilli, and foreign antigens. The phagocytic function of monocytes and macrophages is also influenced by CD4+ T cells.

Like other retroviruses, HIV carries its genetic information in ribonucleic acid (RNA) rather than deoxyribonucleic acid (DNA). The HIV virion is spherical and contains an electron-dense core surrounded by a lipid envelope (Fig. 16.1). The virus core contains the major capsid protein p24, two copies of the genomic RNA, and three viral enzymes (protease, reverse transcriptase, and integrase). Because p24 is the most readily detected antigen, it is the target for the antibodies used in screening for HIV infection. The viral core is surrounded by a matrix protein called p17, which lies beneath the viral envelope. The viral envelope is studded with two viral glycoproteins, gp120 and gp41, which are critical for the infection of cells.

Replication of HIV is depicted in Figure 16.2. Each of these steps provides insights into the development of methods used for preventing or treating the infection. The first step involves the binding of the virus to the CD4+ T cell. Once HIV has entered the bloodstream, it attaches to the surface of a CD4+ T cell by binding to a CD4 receptor that has a high affinity for HIV. However, binding to the CD4 receptor is not sufficient for infection; the virus must also bind with other surface molecules (chemokine coreceptors, such as CCR5 and CXCR4) that bind the gp120 and gp41 envelope glycoproteins. This process is known as attachment. The second step allows for the internalization of the virus. After attachment, the viral envelope peptides fuse to the CD4+ T-cell membrane. Fusion results in an uncoating of the virus, allowing the contents of the viral core (the two single strands of viral RNA and the reverse transcriptase, integrase, and protease enzymes) to enter the host cell. The chemokine coreceptors are critical components of the HIV infection process.

The third step consists of DNA synthesis. In order for HIV to reproduce, it must change its RNA into DNA. It does this by using the reverse transcriptase enzyme. Reverse transcriptase makes a copy of the viral RNA and then in reverse makes another mirror-image copy. The result is double-stranded DNA that carries instructions for viral replication. The fourth step is called integration. During integration, the new DNA enters the nucleus of the CD4+ T cell and, with the help of the

identify antibodies to HIV. These antibodies, unfortunately, do not convey protection against the virus. Although symptoms are not evident, the infection proceeds on a microbiologic level, including the invasion and selective destruction of CD4+ T cells. The continual decline of CD4+ T cells places the person with HIV at high risk for acquiring cancer or other infections.

**KEY POINTS**

**PATHOPHYSIOLOGY OF HIV/AIDS**

- The HIV is a retrovirus that destroys the body’s immune system by taking over and destroying CD4+ T cells.
- In the process of taking over the CD4+ T cell, the virus attaches to receptors on the CD4+ cell, fuses to and enters the cell, incorporates its RNA into the cell’s DNA, and then uses the CD4+ cell’s DNA to reproduce large amounts of HIV, which are released into the blood.
- As the CD4+ T-cell count decreases, the body becomes susceptible to opportunistic infections.

**Classification and Phases of HIV Infection**

**HIV Infection and AIDS Case Definition Classification**

Effective January 1, 1993, the CDC implemented a classification system for HIV infection and an AIDS case definition for adolescents and adults that emphasizes the clinical importance of the CD4+ cell count in the categorization of HIV-related clinical conditions. The classification system defines three categories that correspond to CD4+ cell counts.
Phases of HIV Infection

The typical course of HIV infection is defined by three phases, which usually occur over a period of 8 to 12 years. The three phases are the primary infection phase, chronic asymptomatic or latency phase, and overt AIDS phase.

Many persons, when they are initially infected with HIV, have an acute mononucleosis-like syndrome known as primary infection that can last for a few weeks. This acute phase may include fever, fatigue, myalgias, sore throat, night sweats, gastrointestinal problems, lymphadenopathy, maculopapular rash, and headache (Chart 16.1). During primary infection, there is an increase in viral replication, which leads to very high viral loads, sometimes greater than 1,000,000 copies/mL, and a decrease in the CD4+ T-cell count. The signs and symptoms of primary HIV infection generally manifest about a month post HIV exposure but can show up quicker. After several weeks, the immune system acts to control viral replication and reduces the viral load to a lower level, where it often remains for several years.

People who are diagnosed with HIV infection while they are in the primary infection phase may have a unique opportunity for treatment. Some experts hypothesize that if started early, treatment may reduce the number of long-living HIV-infected cells (e.g., CD4+ memory cells). Early therapy may also protect the functioning of HIV-infected CD4+ T cells and cytotoxic T cells. Finally, early treatment could potentially help maintain a homogeneous viral population that will be better controlled by antiretroviral therapy and the immune system.

The primary phase is followed by a latent period during which the person has no signs or symptoms of illness. The median time of the latent period is about 10 years. During this time, the CD4+ T-cell count falls gradually from the normal range of 800 to 1000 cells/µL to 200 cells/µL or lower. More recent data suggest that the CD4+ T-cell decline may not fall in an even slope based on level of HIV RNA levels and the factors related to variability in the decline in CD4+ cells are under investigation. Some people experience swollen lymph nodes at this time. PGL usually is defined as lymph nodes that are chronically swollen for more than 3 months in at least two locations, not including the groin. The lymph nodes may be sore or visible externally.

The third phase, overt AIDS, occurs when a person has a CD4+ cell count of less than 200 cells/µL or an AIDS-defining illness. Without antiretroviral therapy, this phase can lead to death within 2 to 3 years, or in some cases quicker. The risk of opportunistic infections and death increases significantly when the CD4+ cell count falls below 200 cells/µL (Fig. 16.4).

Clinical Course

The clinical course of HIV varies from person to person. Most, 60% to 70% of those infected with HIV, develop AIDS 10 to 11 years after infection. These people are the typical...
UNIT IV  Infection, Inflammation, and Immunity

**Infection, Inflammation, and Immunity**

...called long-term nonprogressors, who account for 1% of all HIV infections. These people have been infected for at least 8 years, are antiretroviral naive, have high CD4+ cell counts, and usually have very low viral loads. Among this group, there are some people who have spontaneous and sustained virologic suppression without the use of antiretroviral medications. This group of HIV-infected people is currently being investigated to assist in determining the immunologic and virologic interactions that allow those people to maintain virologic suppression of HIV.22

**Opportunistic Infections**

Opportunistic infections begin to occur as the immune system becomes severely compromised. The number of CD4+ T cells directly correlates with the risk of development of opportunistic infections. In addition, the baseline HIV RNA level contributes and serves as an independent risk factor.18

Opportunistic infections involve common organisms that do not produce infection unless there is impaired immune function. Although a person with AIDS may live for many years after the first serious illness, as the immune system fails, these opportunistic illnesses become progressively more severe and difficult to treat.

**Opportunistic Infections**

Opportunistic infections begin to occur as the immune system progresses to AIDS. The number of CD4+ T cells directly correlates with the risk of development of opportunistic infections. In addition, the baseline HIV RNA level contributes and serves as an independent risk factor.18

Opportunistic infections involve common organisms that do not produce infection unless there is impaired immune function. Although a person with AIDS may live for many years after the first serious illness, as the immune system fails, these opportunistic illnesses become progressively more severe and difficult to treat.

Opportunistic infections are most often categorized by the type of organism (e.g., fungal, protozoal, bacterial and mycobacterial, viral). Bacterial and mycobacterial opportunistic infections include bacterial pneumonia, salmonellosis, bartonellosis, *Mycobacterium tuberculosis* (TB), and *Mycobacterium avium–intracellulare* complex (MAC). Fungal opportunistic infections include candidiasis, coccidioidomycosis, cryptococcosis, histoplasmosis, penicilliosis, and pneumocystosis. Protozoal opportunistic infections include cryptosporidiosis, microsporidiosis, isosporiasis, and...
the case of adverse reactions to sulfa compounds) is strongly recommended.\(^\text{18}\)

The symptoms of PCP may be acute or gradually progressive. People may present with complaints of a mild cough, fever, shortness of breath, and weight loss. Physical examination may demonstrate only fever and tachypnea, and breath sounds may be normal. The chest x-ray film may show interstitial infiltrates, but in some people who are PCP+, the x-ray may not be diagnostic. Diagnosis of PCP is made on recognition of the organism in pulmonary secretions. This can be done through examination of induced sputum, bronchoalveolar lavage, transbronchial biopsy, and, rarely, open lung biopsy. A progressive scoring tool has been developed to improve the identification of people who have PCP.\(^\text{17}\)

**Mycobacterium tuberculosis.** Tuberculosis is the leading cause of death for people with HIV infection worldwide and is often the first manifestation of HIV infection. In 2009, 10% of the 13 million Americans with TB were coinfected with HIV.\(^\text{24}\) A number of factors contributed to this increase, including changes in immigration patterns and increased numbers of people living in group settings like prisons, shelters, and nursing homes, but the most profound factor was HIV infection.\(^\text{25}\)

The lungs are the most common site of M. tuberculosis infection, but extrapulmonary infection of the kidney, bone marrow, and other organs also occurs in people with HIV infection. Whether a person has pulmonary or extrapulmonary TB, most people present with fever, night sweats, cough, and weight loss. People infected with M. tuberculosis (i.e., those with positive tuberculin skin test results) are more likely to develop reactivated TB if they become infected with HIV. Coinfected people (i.e., those with both HIV and TB infection) are also more likely to have a rapidly progressive form of TB. Equally important, HIV-infected people with TB coinfection...
usually have an increase in viral load, which decreases the success of TB therapy. They also have an increased number of other opportunistic infections and an increased mortality rate.

Since the late 1960s, most people with TB have responded well to therapy. However, in the 1990s, there were outbreaks of multidrug-resistant (MDR) TB. To be classified as MDR TB, the tubercle bacilli must be resistant to at least isoniazid and rifampin. The tubercle bacilli have recently developed more extensive resistance to include fluoroquinolones and other second-line agents, including capreomycin and kanamycin. These strains of TB are called extensively drug-resistant (XDR) TB. Since the original outbreak of MDR TB in the early 1990s, new cases of MDR TB have declined, largely because of improved infection control practices and the expansion of directly observed therapy programs. Evidence suggests that new vaccines against TB using interferon gamma may protect HIV+ people from HIV-associated TB.25

**Gastrointestinal Manifestations**

Diseases of the gastrointestinal tract are some of the most frequent complications of HIV infection and AIDS. In fact, 80% of people with HIV have some type of gastrointestinal infection during their disease and most frequently it involves the esophagus and/or the colon. If an HIV+ person has a CD4 level of 200 cells/µL, it is common for them to have esophagitis caused by at least one of the following at some point: esophageal candidiasis, CMV infection, and herpes simplex virus infection. People with HIV have colon infections most frequently caused by *Salmonella*, *Shigella*, CMV, and/or *Campylobacter*. Aphthous ulcers presumed secondary to HIV are also common. People experiencing these infections usually complain of painful swallowing or retrosternal pain. The clinical presentation can range from asymptomatic to a complete inability to swallow and resulting dehydration. Endoscopy or barium esophagography is required for definitive diagnosis.

Diarrhea or gastroenteritis is a common complaint in people with HIV infection. In fact, up to 40% of people with HIV experience at least 1 diarrhea event/month and 25% of people with HIV have chronic diarrhea. It is important to evaluate people with HIV for the same common causes of diarrhea as in the general population. The most common protozoal opportunistic infection that causes diarrhea is due to *Cryptosporidium parvum*. The clinical features of cryptosporidiosis can range from mild diarrhea to severe, watery diarrhea with a loss of up to several liters of water per day. The most severe form usually occurs in people with a CD4+ cell count of less than 100 cells/µL.

**Nervous System Manifestations**

HIV infection, particularly in its late stages of severe immunocompromise, leaves the nervous system vulnerable to an array of neurologic disorders, including HIV-associated neurocognitive disorders (HAND), toxoplasmosis, and PML. These disorders can affect the peripheral nervous system or CNS and contribute to the morbidity and mortality of persons with HIV infection.

**HIV-Associated Neurocognitive Disorders.** In 2007, the National Institute of Mental Health and National Institute of Neurological Disorders and Stroke developed a new classification with standardized diagnostic criteria. The three conditions comprising HAND are HIV-associated asymptomatic neurocognitive impairment (ANI), HIV-associated mild neurocognitive disorder (MND), and HIV-associated dementia (HAD, formerly AIDS dementia complex). HAND is a syndrome of cognitive impairment with motor dysfunction or behavioral/psychosocial symptoms associated with HIV infection itself. By 2015, 50% of all people with HIV in the United States will be greater than 50 years of age. Evidence suggests that inflammation and HIV+ status influence accelerated aging and also increase the risk of acquiring a neurodegenerative disorder such as Parkinson and/or Alzheimer disease. There are no known cause and effect data that use of long-term antiretrovirals also augments the chance of neurodegenerative disease, but there is suspicion. Research does support the relationship between long-term use of antiretrovirals and increased cardiovascular disease with in people who are HIV+.30

HAD is usually a late complication of HIV infection. The clinical features of HAD are impairment of attention and concentration, slowing of mental speed and agility, slowing of motor speed, and apathic behavior. The diagnosis of HAD is one of exclusion, and all other potential etiologies need to be excluded. Treatment of HAD consists of HAART to decrease symptoms and may result in significant improvement of both motor and cognitive skills. Family history of dementia also is linked with more serious loss of neuropsychological functioning with HIV+ status.31

**Toxoplasmosis.** Toxoplasmosis is a common opportunistic infection in people with AIDS. *T. gondii* is a parasite that most often affects the CNS (Fig. 16.7). Toxoplasmosis usually is a reactivation of a latent *T. gondii* infection that has been dormant in the CNS and then is manifested once immunological...
function is decreased. The typical presentation includes fever, headaches, and neurologic dysfunction, including confusion and lethargy, visual disturbances, and seizures. Computed tomography scans or, preferably, magnetic resonance imaging (MRI) should be performed immediately to detect the presence of neurologic lesions. Treatment with sulfadiazine, dapsone–pyrimethamine, and leucovorin has proven effective against T. gondii when the CD4+ cell count falls below 100 cells/µL.33

Progressive Multifocal Leukoencephalopathy. PML is a demyelinating disease of the white matter of the brain caused by the JC virus, a DNA polyoma virus that attacks the oligodendrocytes14 (Fig. 16.8). PML is characterized by progressive limb weakness, sensory loss, difficulty controlling the digits, visual disturbances, changes in mental status, ataxia, diplopia, and seizures.14 The mortality rate is high, and the average survival time is approximately 6 months.14 Diagnosis is based on clinical findings and an MRI and confirmed by the presence of the JC virus.14 There is no proven cure for PML, but improvement can occur after starting effective HAART. However, in people who develop PML while on HAART, the outcome may be worse secondary to immune reconstitution syndrome.32

Cancers and Malignancies
People with AIDS have a high incidence of certain malignancies, especially KS, non-Hodgkin lymphoma, and noninvasive cervical carcinoma. The increased incidence of malignancies probably is a function of impaired cell-mediated immunity. As people with HIV infection are living longer, there have been reports of the increasing incidence of age- and gender-specific malignancies.34 People with HIV infection appear to have an increased risk of lung cancer even after adjusting for tobacco history and other malignancies.35 Non–AIDS-defining malignancies account for more morbidity and mortality than AIDS-defining malignancies in the antiretroviral therapy era.35 Traditional risk factors play a significant role in the increased risk of non–AIDS-defining malignancies for HIV-infected individuals, but do not entirely explain the excess cancer risk.35 Increased incidences of Hodgkin; lung, head and neck, and conjunctival cancers; and hemopathies have been demonstrated in the post-HAART era.35

Kaposi Sarcoma. KS is a malignancy of the endothelial cells that line small blood vessels throughout the body.14 An opportunistic cancer, KS occurs in people who are immunosuppressed (e.g., transplant recipients or people with AIDS). KS was one of the first opportunistic cancers associated with AIDS and still is the most frequent malignancy related to HIV infection.14 KS is associated with a herpesvirus (herpesvirus 8 [HHV8]) and is also called KS-associated herpes virus (KSHV).14 Over 95% of KS lesions, regardless of the source or clinical subtype, have reportedly been found to be infected with KSHV. HHV8 is also linked with Castleman disease and primary effusion lymphomas.14

The lesions of KS can be found on the skin and in the oral cavity, gastrointestinal tract, and the lungs. Many people with skin lesions also have gastrointestinal lesions. The disease usually begins as one or more macules, papules, or violet skin lesions that enlarge and become darker (Fig. 16.9). They may enlarge to form raised plaques or tumors (Fig. 16.10). These irregularly shaped tumors can range from 0.8 to 1.5 inches in size. Tumor nodules frequently are located on the trunk, neck, and head, especially the tip of the nose. They usually are painless in the early stages, but discomfort may develop as the tumor develops. Invasion of internal organs, including the lungs, gastrointestinal tract, and lymphatic system, commonly occurs. The progression of KS may be slow or rapid.

A presumptive diagnosis of KS usually is made based on visual identification of red or violet skin or oral lesions.14,36 Biopsy of at least one lesion should be done to establish the diagnosis and to distinguish KS from other skin lesions that may resemble it. Diagnosis of solitary gastrointestinal or pulmonary KS is more difficult because endoscopy and bronchoscopy are needed for diagnosis and biopsy of such lesions is contraindicated because of the risk of severe bleeding. Effective HAART is the treatment of choice for localized KS.
Metabolic and Morphologic Disorders

A wide range of metabolic and morphologic disorders is associated with HIV infection, including lipoatrophy and mitochondrial disorders, lipohypertrophy, hypercholesterolemia, hypertriglyceridemia, insulin resistance, and impaired glucose tolerance. The term lipodystrophy is frequently used to describe the body composition changes with or without the other metabolic derangements. Metabolic complications among people with HIV infection on HAART have been increasing since the introduction of potent HAART. Insulin resistance and diabetes appear to be higher among people with HIV infection compared with the general population, although traditional risk factors contribute significantly. Insulin resistance and diabetes also appear to be more associated with the use of specific nucleosides in combination with protease inhibitors rather than just the protease inhibitors, as initially thought. It is still not known why insulin resistance occurs in people with HIV infection, and most experts believe it is secondary to dysregulation of metabolic pathways or to indirect effects through mitochondrial toxicity linked to adipocyte toxicity. Treatment of insulin resistance is the same as for people without HIV infection and includes a healthy, balanced diet; exercise; and weight loss, if needed.

Non-Hodgkin Lymphoma

Non-Hodgkin lymphoma develops in 3% to 4% of people with HIV infection. The clinical features are fever, night sweats, and weight loss. Because the manifestations of non-Hodgkin lymphoma are similar to those of other opportunistic infections, diagnosis often is difficult. Diagnosis can be made by biopsy of the affected tissue. Treatment consists of aggressive combination chemotherapy that may include intrathecal chemotherapy.

Noninvasive Cervical and Anal Carcinoma

The HPV has been linked to the development of cervical carcinoma and anal carcinoma in both HIV-positive men and women. Women with HIV infection experience a higher incidence of cervical intraepithelial neoplasia (CIN) than non–HIV-infected women. HIV-infected women and men often experience persistent and recurrent HPV-associated anogenital disease. Occurrence of cervical dysplasia is detected by Papanicolaou smear and cervical colposcopy and can be also used to screen men for anal cancer. Gardasil and Cervarix are two available vaccines developed to provide immunity to HPV specifically HPV-16 and HPV-18. The safety and immunogenicity of this vaccine among HIV-infected men and women are being studied.

Wasting Syndrome

The wasting syndrome is an AIDS-defining illness and is common in people with HIV infection or AIDS. Wasting is characterized by involuntary weight loss of at least 10% of baseline body weight in the presence of diarrhea, more than two stools per day, or chronic weakness and a fever. This diagnosis is made when no other opportunistic infections or neoplasms can be identified as causing these symptoms. Factors that contribute to wasting are anorexia, metabolic abnormalities, endocrine dysfunction, gut barrier disorders, inflammation of gut-associated lymph tissue, malabsorption, and cytokine dysregulation. Treatment for wasting includes nutritional interventions like oral supplements or enteral or parenteral nutrition.
Before beginning antiretroviral therapy, a fasting lipid panel should be drawn, repeated in 3 to 6 months, and then repeated yearly.\textsuperscript{45} One strategy in attempting to correct or reverse these abnormalities is to switch the HAART regimen to an equally suppressive one that contains medications less likely to cause dyslipidemia. It is important to carefully weigh the risks of potential loss of virologic suppression when alterations in HAART are made. The statins are the recommended medications to manage elevated LDL cholesterol. However, caution must be used because there can be serious drug-metabolizing interactions between the protease inhibitors, NNRTIs, and statins.

**Lipodystrophy.** Lipodystrophy related to HIV infection includes symptoms that fall into two categories: changes in body composition and metabolic changes.\textsuperscript{45} The alterations in body appearance are an increase in abdominal girth, buffalo hump development (abnormal distribution of fat in the supravclavicular area), wasting of fat from the face and extremities, and breast enlargement in men and women. Most people experience either lipohypertrophy or lipoatrophy. The metabolic changes include elevated serum cholesterol, low HDL cholesterol, elevated triglyceride levels, and insulin resistance. Originally attributed to the use of protease inhibitors, the pathogenesis of these metabolic derangements is complex and there may be multiple confounding factors.\textsuperscript{45}

Diagnosis of lipodystrophy is difficult because it may depend on subjective measures of reports of alteration in body shape and also because the term has not been standardized. The Lipodystrophy Case Definition Study Group developed a definition that incorporated 10 clinical, metabolic, and body composition variables that can diagnose lipodystrophy with 80\% accuracy.\textsuperscript{46} The Study of Fat Redistribution and Metabolic Change in HIV Infection (FRAM) also developed a model to define lipodystrophy.\textsuperscript{47} However, neither study's definitions have gained wide acceptance, and most clinicians prefer to describe the spectrum of signs and symptoms their patients experience. Therefore, it is critical when interpreting the vast number of clinical trials that one note the definition used for that particular study. Some preliminary data are available on the use of recombinant human growth hormone to decrease visceral adipose tissue and subcutaneous adipose tissue.\textsuperscript{48} Metformin and thiazolidinedione, oral antidiabetic drugs, have also been studied; results have been inconsistent. Some experts recommend switching to a HAART regimen that is not protease inhibitor–based for the treatment of lipohypertrophy, although this has not resulted in consistent results either. There is some evidence that switching from a thymidine analog to a nonthymidine analog may improve lipatrophy. Surgical intervention (e.g., liposuction, implantation or injection of synthetic substances) has been used with some success.

**Mitochondrial Disorders.** The mitochondria control many of the oxidative chemical reactions that release energy from glucose and other organic molecules. The mitochondria transform this newly released energy into adenosine triphosphate (ATP), which cells use as an energy source. In the absence of normal mitochondrial function, cells revert to anaerobic metabolism with generation of lactic acid. The mitochondrial disorders seen in people with HIV infection are attributed to NRTIs, particularly the thymidine analogs.\textsuperscript{45} The most common presentations are lipatrophy and peripheral neuropathy, although people may not experience both. People may also present with nonspecific gastrointestinal symptoms, including nausea, vomiting, and abdominal pain. They may develop altered liver function and lactic acidosis. Since the recognition of the ascending polynueopathy syndrome and reports of hepatic failure due to combination therapy with stavudine and didanosine, reports of life-threatening events due to mitochondrial toxicities have dramatically decreased.

**IN SUMMARY**

HIV is a retrovirus that infects the body’s CD4\(^+\) T cells and macrophages. HIV genetic material becomes integrated into the host cell DNA, so new HIV can be made.

Manifestations of infection, such as acute mononucleosilike symptoms, may occur shortly after infection, and this is followed by a latent phase that may last for many years. The end of the latent period is marked by the onset of opportunistic infections and cancers as the person is diagnosed with AIDS. The complications of these infections can manifest throughout the respiratory, gastrointestinal, and nervous systems and can include pneumonia, esophagitis, diarrhea, gastroenteritis, tumors, wasting syndrome, altered mental status, seizures, motor deficits, and metabolic disorders.

**PREVENTION, DIAGNOSIS, AND TREATMENT**

After completing this section of the chapter, you should be able to meet the following objectives:

- Differentiate between the enzyme immunoassay (enzyme-linked immunosorbent assay) and Western blot antibody detection tests for HIV infection.
- Compare the actions of the reverse transcriptase inhibitors (e.g., nucleoside/nucleotide analog reverse transcriptase inhibitors, nonnucleoside reverse transcriptase inhibitors), protease inhibitors, and fusion inhibitors in terms of controlling HIV replication.

Since the first description of AIDS, considerable strides have been made in understanding the pathophysiology of the disease. The virus and its mechanism of action, HIV antibody screening tests, and some treatment methods were discovered within a few years after the recognition of the first cases. Further progress in understanding the pathophysiology of AIDS and the development of more powerful treatments continues to be made.
Prevention

Because there is no cure for HIV infection or AIDS, adopting risk-free or low-risk behavior is the best protection against the disease. Abstinence and long-term, mutually monogamous sexual relationships between two uninfected partners are the best ways to avoid HIV infection and other STDs. Correct and consistent use of latex condoms can provide protection from HIV by not allowing contact with semen or vaginal secretions during intercourse. Natural or lambskin condoms do not provide the same protection from HIV as latex because of the larger pores in the material. Only water-based lubricants should be used with condoms; petroleum (oil-based) products weaken the structure of the latex.

Avoiding recreational IV drug use and particularly avoiding the practice of using syringes that may have been used by another person are important to HIV prevention. Medical and public health authorities recommend that people who choose to inject drugs use a new sterile syringe for each injection or, if this is not possible, clean their syringes thoroughly with a household bleach mixture. Other substances that alter inhibitions can lead to risky sexual behavior and increase the risk of exposure to HIV. The addictive nature of many recreational drugs can lead to an increase in the frequency of unsafe sexual behavior and the number of partners as the user engages in sex in exchange for money or drugs. People concerned about their risk should be encouraged to get information and counseling and be tested to find out their infection status.

Public health programs in the United States have been profoundly affected by the HIV epidemic. Although standard methods for disease intervention and statistical analysis are applied to HIV infection, public health programs have become more responsive to community concerns, confidentiality, and long-term follow-up of people as a direct result of the HIV epidemic. In 2006, the CDC issued an update on the recommendations for testing for HIV. The CDC recommends that all people between 13 and 64 years of age should be routinely screened for HIV. Anyone who is at continued risk for HIV infection should be tested at least annually. Those who are at high risk, including injection drug users and their partners, people who exchange sex for money or drugs, and anyone who has had more than one sex partner since the last HIV test, should be tested more frequently.

The essential elements of any HIV prevention/counseling interaction include a personalized risk assessment and prevention plan. Education and behavioral intervention continue to be the mainstays of HIV prevention programs. Individual risk assessment and education regarding HIV transmission and possible prevention techniques or skills are delivered to persons in clinical settings and to those at high risk of infection in community settings. Community-wide education is provided in schools, the workplace, and the media. Training for professionals can have an impact on the spread of HIV and is an important element of prevention. The constant addition of new information on HIV makes prevention an ever-changing and challenging endeavor.

Diagnostic Methods

The diagnostic methods used for HIV infection include laboratory methods to determine infection and clinical methods to evaluate the progression of the disease. The most accurate and inexpensive method for identifying HIV infection is the HIV antibody test. The first commercial assays for HIV were introduced in 1985 to screen donated blood. Since then, use of antibody detection tests has been expanded to include evaluating persons at increased risk for HIV infection. The HIV antibody test procedure consists of screening with an enzyme immunoassay (EIA), also known as enzyme-linked immunosorbent assay (ELISA), followed by a confirmatory test, the Western blot assay, which is performed if the EIA is positive. In light of the psychosocial issues related to HIV infection and AIDS, sensitivity and confidentiality must be maintained whenever testing is implemented.

The EIA detects antibodies produced in response to HIV infection. In an EIA, when blood is added, antibodies to HIV bind to HIV antigens. The antigen–antibody complex is then detected using an anti–human immunoglobulin G (IgG) antibody conjugated to an enzyme such as alkaline phosphatase. A substrate is then added from which the enzyme produces a color reaction. Color development, indicating the amount of HIV antibodies found, is measured. The test is considered reactive, or positive, if color is produced and negative, or non-reactive, if there is no color. EIA tests have high false-positive rates, so samples that are repeatedly reactive are tested by a confirmatory test such as the Western blot.

The Western blot test is more specific than the EIA, and in the case of a false-positive EIA result, the Western blot test can identify the person as uninfected. The Western blot is a more sensitive assay that looks for the presence of antibodies to specific viral antigens. For the test, HIV antigens are separated by electrophoresis based on their weight and then transferred to nitrocellulose paper and arranged in strips, with larger proteins at the top and smaller proteins at the bottom. The serum sample is then added. If HIV antibodies are present, they bind with the specific viral antigen on the paper. An enzyme and substrate are then added to produce a color reaction as in the EIA. If there are no colored bands present, the test is negative. A test is positive when certain combinations of bands are present. A test can be indeterminate if there are bands present but they do not meet the criteria for a positive test result. An indeterminate or false-positive test result can occur during the window period before seroconversion. When a serum antibody test result is reactive or borderline by EIA and positive by Western blot, the person is considered to be infected with HIV. When an EIA is reactive and the Western blot is negative, the person in not infected with HIV. Both tests are important because, in some situations, misinformation can be generated by EIA testing alone because there are many situations that can produce a false-positive (Chart 16.2) or a false-negative EIA result. The Western blot test therefore is essential to determine which people with positive EIA results are truly infected.

Approximately 16 to 22 million people in the United States are tested annually for HIV. New technology has led
to new forms of testing, like the oral test, home testing kits, and the new rapid blood test. Oral fluids contain antibodies to HIV. Home HIV testing kits can be bought over the counter. The kits, approved by the FDA, allow people to collect their own blood sample through a finger-stick process, mail the specimen to a laboratory for EIA and confirmatory Western blot tests, and receive results by telephone in 3 to 7 days. The use of a rapid test should facilitate people receiving the results of their HIV test more regularly because they do not need to return for their test results 2 weeks later unless it is positive or there is concern that the person may be in the window period before seroconversion and need retesting in the future.

**Polymerase chain reaction (PCR)** is a technique for detecting HIV DNA. PCR detects the presence of the virus rather than the antibody to the virus, which the EIA and Western blot tests detect. PCR is useful in diagnosing HIV infection in infants born to infected mothers because these infants have their mothers’ HIV antibody regardless of whether the children are infected. Because the amount of viral DNA in the HIV-infected cell is small compared with the amount of human DNA, direct detection of viral genetic material is difficult. PCR is a method for amplifying the viral DNA up to 1 million times or more to increase the probability of detection.

### Chart 16.2 Causes of False-Positive or False-Negative HIV ELISA Test Results

**False-Positive Results**
- Hematologic malignant disorders (e.g., malignant melanoma)
- DNA viral infections (e.g., infectious mononucleosis [Epstein-Barr virus])
- Autoimmune disorders
- Primary biliary cirrhosis
- Immunizations (e.g., influenza, hepatitis)
- Passive transfer of HIV antibodies (mother to infant)
- Antibodies to class II leukocytes
- Chronic renal failure/renal transplant
- Stevens-Johnson syndrome
- Positive rapid plasma reagin test

**False-Negative Results**
- “Window” period after infection
- Immunosuppression therapy
- Replacement transfusion
- B cell dysfunction
- Bone marrow transplant
- Contamination of specimen with starch powder from gloves
- Use of kits that detect primary antibody to the p24 viral core protein

### Treatment
There is no cure for HIV infection. The medications that are currently available to treat HIV infection decrease the amount of virus in the body, but they do not eradicate HIV. The management of HIV infection has changed dramatically since the mid-1990s. This change is due to a better understanding of the pathogenesis of HIV, the emergence of viral load testing, and the increased number of medications available to fight the virus. After HIV infection is confirmed, a baseline evaluation should be done. This evaluation should include a complete history and physical examination and baseline laboratory tests including a complete blood count (CBC) with differential. Routine follow-up care of a stable, asymptomatic person infected with HIV should include a history and physical examination along with CD4+ cell count and viral load testing every 3 to 4 months. People who are symptomatic may need to be seen more frequently.

Therapeutic interventions are determined by the level of disease activity based on the viral load, the degree of immunodeficiency based on the CD4+ cell count, and the appearance of specific opportunistic infections. The National Institutes of Health is annually revising the Use of Antiretroviral Agents for HIV-1-Infected Adults and Adolescents. Because of frequent advances in the management of HIV infection, primary care providers must be prepared to update their knowledge of diagnosis, testing, evaluation, and medical intervention. The treatment of HIV infection is one of the most rapidly evolving fields in medicine. The Infectious Diseases Society of America/HIV Medicine Association, the CDC, the Department of Health and Human Services, and the U.S. Public Health Service regularly issue guidelines to assist clinicians in caring for people with HIV infection.

### Pharmacologic Management
Because different drugs act on various stages of the replication cycle, optimal treatment includes a combination of drugs. The first drug that was approved by the FDA for the treatment of HIV was zidovudine in 1987. Since then, an increasing number of therapeutics has been approved by the FDA for treatment of HIV infection. There currently are five classes of HIV antiretroviral medications:

- Reverse transcriptase inhibitors
- Protease inhibitors
- Fusion/entry inhibitors
- Integrase inhibitors
- Multidrug combination products

Each type of agent attempts to interrupt viral replication at a different point. Maturation inhibitors are still in development and if they are effective their action is to block the HIV virus from forming an outer coat and from emerging from the cells.

**Reverse transcriptase inhibitors** inhibit HIV replication by acting on the enzyme reverse transcriptase. There are three types of HIV medications that work on this enzyme: nucleoside analog reverse transcriptase inhibitors (NRTIs), nucleotide
reverse transcriptase inhibitors (NRTIs), and non-nucleoside reverse transcriptase inhibitors (NNRTIs). Nucleoside analog reverse transcriptase inhibitors and nucleotide reverse transcriptase inhibitors act by blocking the elongation of the DNA chain by stopping more nucleosides from being added. Nonnucleoside reverse transcriptase inhibitors work by binding to the reverse transcriptase enzyme so it cannot copy the virus’s RNA into DNA.

_protease inhibitors_ bind to the protease enzyme and inhibit its action. This inhibition prevents the cleavage of the polypeptide chain into individual proteins, which would be used to construct the new virus. Because the information inside the nucleus is not put together properly, the new viruses that are released into the body are immature and noninfectious.

The two newest classes of antiretroviral therapy are the _entry inhibitors_ and _integrase inhibitors_. The entry inhibitors prevent HIV from entering or fusing with the CD4+ cell, thus blocking the virus from inserting its genetic information into the CD4+ T cell. There are two types of entry inhibitors: _fusion inhibitors_ and _CCR5 antagonists_. Integrase inhibitors block the integration step of the viral cycle, thus preventing the HIV genome from integrating into the host’s genome. In December 2011 another HIV vaccine has been given Federal Drug Administration approval from a Canadian university with the first phase of testing beginning in early 2012. Previous HIV vaccines have all failed.

Preventing and Treating Opportunistic Infections

Advise people with HIV infection to avoid infections as much as possible and seek evaluation promptly when they occur. Immunization is important because people infected with HIV are at risk for contracting other infectious diseases. Some of these diseases can be avoided by vaccination while the immune system’s responsiveness is relatively intact. People with asymptomatic HIV infection and CD4+ cell counts greater than 200 cells/µL should be vaccinated against measles, mumps, and rubella. Pneumococcal vaccine should be given once, as soon as possible after HIV infection is diagnosed, and then every 10 years, and influenza vaccine should be given yearly. Live-virus vaccines should not be given to people with HIV infection. However, there is much interest in the possibility of vaccinating people infected with HIV with the varicella–zoster virus (VZV) vaccine to decrease the risk of VZV disease recurrences or shingles.

HIV infection is diagnosed using the EIA or rapid test together with the Western blot assay, both of which are antibody detection tests. The emotional stress, feelings of isolation, and sadness experienced by the person with HIV infection or AIDS can be overwhelming, but most persons adjust to living with HIV infection. Diagnosis and treatment of cognitive and affective disorders are an essential part of ongoing care for the HIV-infected person. Appropriate treatment should be made available when alcohol or other drug dependence is noted.

The management of HIV infection/AIDS incorporates five different drug classifications including the combination therapy of HAART, early recognition and treatment of opportunistic infections and other clinical disorders, and surveillance of HIV profile.

### IN SUMMARY

Because there is no cure for HIV infection, risk-free or low-risk behavior is the best protection against it. Abstinence or long-term, mutually monogamous sexual relationships between two uninfected partners, use of condoms, avoiding drug use, and the use of sterile syringes if drug use cannot be avoided are essential to halting the transmission of HIV.

### HIV INFECTION IN PREGNANCY AND IN INFANTS AND CHILDREN

After completing this section of the chapter, you should be able to meet the following objectives:

- Discuss the vertical transmission of HIV from mother to child and recommended prevention measures.
- Compare the progress of HIV infection in infants and children with HIV infection in adults.

Early in the epidemic, children who acquired HIV could have become infected through blood products or perinatally. Now, almost all of the children who become infected with HIV at a young age in the United States get the infection perinatally. Fortunately, the incidence of perinatally infected children in the United States has markedly decreased by 90%. Infected women may transmit the virus to their offspring in utero, during labor and delivery, or through breast milk. The risk of transmission is increased if the mother has advanced HIV disease as evidenced by low CD4+ cell counts or high levels of HIV in the blood (high viral load), if there was prolonged time from rupture of membranes to delivery, if the mother breast-feeds the child, or if there is increased exposure of the fetus to maternal blood.

### KEY POINTS

**HIV INFECTION IN PREGNANCY AND IN INFANTS AND CHILDREN**

- HIV can be passed from mother to infant during labor and delivery or through breast-feeding.
- The course of HIV infection is different for children than adults.
Late stages, PCP occurs early in children, with the peak age of onset at 3 to 6 months. For this reason, prophylaxis with trimethoprim–sulfamethoxazole is started by 4 to 6 weeks for all infants born to HIV-infected mothers, regardless of their CD4+ cell count or infection status.

**IN SUMMARY**

Infected women may transmit the virus to their offspring in utero, during labor and delivery, or through breast milk. It is recommended that all pregnant women be tested for HIV at the time of diagnosis of pregnancy and again at the time of labor and delivery. Diagnosis of HIV infection in children born to HIV-infected mothers is complicated by the presence of maternal HIV antibody, which crosses the placenta to the fetus. This antibody usually disappears within 18 months in uninfected children. Administration of antiretroviral therapy to the mother during pregnancy and labor and delivery and to the infant when it is born decreases perinatal transmission.

**Preventing Perinatal HIV Transmission**

All women who are HIV+ are put on zidovudine during pregnancy or even just during labor and delivery if they have not had prenatal care, to prevent perinatal transmission to the infant when it is born. In fact, all women are recommended to be tested for HIV status when they become pregnant as well as at the time of labor and delivery since it is crucial if they are HIV+ that they received the zidovudine. This is done because it has now been found that women receiving antiretroviral therapy who also have a viral load less than 1000 copies/mL have very low rates of perinatal transmission. One caveat to antiretroviral therapy in pregnancy is that efavirenz cannot be used during the first trimester because it is a teratogen, causing neural tube defects. Benefits of voluntary testing for mothers and newborns include reduced morbidity because of intensive treatment and supportive health care, the opportunity for early antiretroviral therapy for mother and child, and information regarding the risk of transmission from breast milk. Because pregnant women in less developed countries do not always have access to zidovudine, studies are being conducted to determine if other, simpler and less expensive, antiretroviral regimens can be used to decrease HIV transmission from mother to infant.

**Diagnosis of HIV Infection in Children**

Diagnosis of HIV infection in children born to HIV-infected mothers is complicated by the fact that infants have the maternal anti-HIV IgG antibody for approximately 6 months. Consequently, infants born to HIV-infected women can be HIV antibody positive by ELISA for up to 18 months of age even though they are not infected with HIV. PCR testing for HIV DNA is used most often to diagnose HIV infection in infants younger than 18 months of age. Two positive PCR tests for HIV DNA are needed to diagnose a child with HIV infection. Children born to mothers with HIV infection are considered uninfected if they become HIV antibody negative after 6 months of age, have no other laboratory evidence of HIV infection, and have not met the surveillance case definition criteria for AIDS in children.

**Clinical Presentation of HIV Infection in Children**

Children may have a different clinical presentation of HIV infection than adults. Failure to thrive, CNS abnormalities, and developmental delays are the most prominent primary manifestations of HIV infection in children. Infants born with HIV infection usually weigh less and are shorter than noninfected infants. A major cause of early mortality for HIV-infected children is PCP, which may also be transmitted vertically. As opposed to adults, in whom PCP occurs in the late stages, PCP occurs early in children, with the peak age of onset at 3 to 6 months. For this reason, prophylaxis with trimethoprim–sulfamethoxazole is started by 4 to 6 weeks for all infants born to HIV-infected mothers, regardless of their CD4+ cell count or infection status.

**REVIEW EXERCISES**

1. A 29-year-old woman presents to the clinic for her initial obstetrics visit, about 10 weeks into her pregnancy.
   A. This woman is in a monogamous relationship. Should an HIV test be a part of her initial blood work? Why?
   B. The woman’s HIV test comes back positive. What should be done to decrease the risk of her passing on HIV to her infant?
   C. The infant is born, and its initial antibody test is positive. Does this mean the infant is infected? How is the diagnosis of HIV infection in an infant younger than 18 months made, and why is this different than the diagnosis for adults?

2. A 40-year-old man presents to the clinic very short of breath, and based on radiography and examination, he is diagnosed with PCP. His provider does an HIV test, which is positive. On further testing, the man’s CD4+ count is found to be 100 cells/µL and his viral load is 250,000 copies/mL.
   A. Why did the provider do an HIV test after the man was diagnosed with PCP?
   B. Is there a way to prevent PCP?
   C. What CDC classification does this man fall into based on his CD4+ count and symptomatology? Why?

A 22-year-old female college student, Ms. Ulrie, presents with blurry vision, upper extremity weakness, and tingling, and numbness in both hands. Ms. Ulrie is worried that she might have multiple sclerosis (MS), because her maternal grandmother suffered from this disorder. On neurological examination, she has blurry vision in the right eye, motor weakness, and a feeling of pins and needles in both hands. Blood investigations are normal, including hemoglobin concentration, overall and differential white cell count, erythrocyte sedimentation rate, vitamin B12 and folate levels, and syphilis serology. Magnetic resonance imaging (MRI) reveals one to two periventricular demyelinated plaques. The cerebrospinal fluid (CSF) extracted by lumbar puncture contains normal amounts of protein (0.40 mg/dL) and lymphocytes (three cells observed in the sample). Further analysis of the CSF by gel electrophoresis reveals the presence of multiple oligoclonal bands. These bands represent specific types of immunoglobulins and are rare in individuals who do not have MS or a similar inflammatory disorder of the central nervous system. They are present in 90% of people with multiple sclerosis. Ms. Ulrie’s symptoms and test results lead to a diagnosis of MS. Chapters 17 and 19 discuss the pathophysiology of MS and the impact it will have on Ms. Ulrie’s life in greater detail.
The major functions of the nervous system include detecting, analyzing, and transmitting information. The sensory system, integrated by the brain, generates signals to motor and autonomic systems to control movement and visceral and endocrine functions. These actions are controlled by neurons, forming a signaling network that includes a motor and sensory system. The nervous system can be divided into two components—the central nervous system (CNS) and the peripheral nervous system (PNS). The CNS consists of the brain and spinal cord. The PNS consists of cranial nerves (CNs) originating from the brain and spinal nerves originating from the spinal cord. Nerve cells of both the CNS and PNS form incoming (afferent) sensory pathways and outgoing (efferent) motor pathways.

This chapter is divided into five parts:

1. Nervous tissue cells
2. Neurophysiology
3. Developmental organization of the nervous system
4. Structure and function of the spinal cord and brain
5. Autonomic nervous system (ANS)

NERVOUS TISSUE CELLS

After completing this chapter, you should be able to meet the following objectives:

• Distinguish between the functions of the neurons and neuroglial cells of the nervous system.
• Describe the structure and function of the three parts of a neuron.
• Describe the metabolic requirements of nervous tissue.

Nervous tissue contains two types of cells—neurons and neuroglial cells. The neurons are the functional cells of the nervous system. They exhibit excitability and conduct impulses for the nervous system to function. The neuroglial cells protect the nervous system and provide support for the neurons.
**KEY POINTS**

**THE STRUCTURAL ORGANIZATION OF THE NERVOUS SYSTEM**

- The nervous system is divided into two parts—the CNS, consisting of the brain and spinal cord, which are located in the skull and spinal column, and the PNS, which is located outside these structures.
- The nervous system contains two major types of cells: neurons, which are functioning cells of the nervous system, and neuroglial cells, which protect the nervous system and supply metabolic support.

**Neurons**

Neurons are the functioning cells of the nervous system. Afferent (sensory) neurons transmit information to the CNS, whereas efferent (motor) neurons carry information away from the CNS (Fig. 17.1). Interspersed between the afferent and efferent neurons is a network of interconnecting neurons (also called interneurons or internuncial neurons) that modulate and control the body’s response to sensory input from the internal and external environments.

Neurons have three distinct parts—the cell body, the dendrites, and the axons. These structures form the functional connections, or synapses, with other nerve cells, with receptor cells, or with effector cells. Axonal processes are particularly designed for rapid communication with other neurons and the many body structures innervated by the nervous system.

The cell body (soma) of a neuron contains a large, vesicular nucleus with one or more distinct nucleoli and a well-developed rough endoplasmic reticulum. A neuron’s nucleus has the same deoxyribonucleic acid (DNA) and genetic code content present in other cells of the body. Its nucleolus, which is composed of portions of several chromosomes, produces ribonucleic acid (RNA) needed for protein synthesis. The cytoplasm contains large masses of ribosomes that are prominent in most neurons. These acidic RNA masses, which are involved in protein synthesis, stain as dark Nissl bodies with basic histologic stains (see Fig. 17.1).

Dendrites are multiple, short, branched extensions of the nerve cell body. They conduct information toward the cell body and are the main source of information for the neuron. The dendrites and cell body are studded with synaptic terminals that communicate with axons and dendrites of other neurons.

Axons are long efferent processes that project from the cell body. Most neurons have only one axon. However, axons may exhibit multiple branching that results in many axonal terminals. The axon of a neuron conducts nerve impulses from the cell body to its synapse. The axon also provides a physical conduit for the transport of materials between the cell body and the synaptic terminals of the axon. The cell body of the neuron is equipped for a high level of metabolic activity. This is necessary because the cell body must synthesize the cytoplasmic and membrane constituents required to maintain the function of the cell body plus the many proteins and other cytoplasmic constituents required to maintain the function of the cell body plus the many proteins and other cytoplasmic constituents required to maintain the function of the cell body.
materials used by the axon and its synaptic terminals. Axons can be very short (0.1 mm) or very long (3.0 m).\(^2\) Axon diameter can vary. Large-diameter axons conduct impulses rapidly, and smaller-diameter axons conduct impulses slowly.

Transportation of materials occurs from the cell body to the axon terminals (anterograde transport) and to a lesser extent in the opposite direction (retrograde transport). The anterograde component consists of fast and slow components. Fast anterograde systems transport molecules such as neurosecretory granules by an energy-dependent system at the rate of 100 to 400 mm/day.\(^2\) Another component of the fast anterograde system transports organelles, including mitochondria. The antidiuretic hormone and oxytocin use the fast anterograde system to travel from hypothalamic neurons through their axons to the posterior pituitary, where the hormones are released into the blood. The slow anterograde component transports materials such as tubulin and cytoplasmic enzymes at a rate of 0.1 to 3.0 mm/day.\(^2\) A fast retrograde component of axonal transport carries materials that are shipped back to the cell body for degradation or reuse. Although much of this material is degraded in lysosomes, retrograde transport is also used to deliver signals to the cell body.

Two motor proteins (kinesin and dynein) are involved in the transport process. Kinesins are generally plus-end-directed motor proteins that transport their cargo anterograde toward the synapse. Cytoplasmic dyneins are minus-end-directed motor proteins that transport their cargo retrograde toward the cell body.

### Neuroglial Cells

The neuroglial cells of the nervous system, including the several types of neuroglial cells of the CNS, and the Schwann and satellite cells of the PNS, give the neurons protection and metabolic support. The neuroglial cells segregate the neurons into isolated metabolic compartments, which are required for normal neural function. Some types of neuroglial cells (astrocytes) help to form the blood–brain barrier that prevents toxic materials in the blood from entering the brain.

Two types of neuroglial cells (oligodendrocytes in the CNS and Schwann cells in the PNS) produce the myelin used to insulate nerve cell processes and increase the velocity of nerve impulse conduction. Myelin has a high lipid content, which gives it a whitish color, and the name white matter is given to the masses of myelinated fibers in the spinal cord and brain. Besides its role in increasing conduction velocity, the myelin sheath is essential for the survival of larger neuronal processes, perhaps by the secretion of neurotrophic compounds. Myelin formation is essentially the same in both the CNS and PNS. Both contain myelin basic protein, and both involve the winding of plasma membranes around the nerve fiber. During the wrapping of myelin, the cytoplasm between two adjacent inner leaflets of the plasma membrane is expelled. The two adjacent inner leaflets and any remaining cytoplasm appear as a dark line called the *minor dense line*. Likewise, during the wrapping of the plasma membranes to form myelin, adjacent outer plasma membrane leaflets become opposed, creating the interperiod or *major dense line*.

In some pathologic conditions, the myelin may degenerate or be destroyed. This leaves a section of the axonal process without myelin (demyelinated) while leaving the nearby oligodendroglial or Schwann cells intact. Unless remyelination takes place, the axon eventually dies. In one study focused on multiple sclerosis (a disease characterized by demyelinated lesions or plaques) in the CNS, significantly more of the demyelinated lesions remyelinated in early multiple sclerosis compared to the chronic type of multiple sclerosis. The study also found that the anatomic location of the demyelinated lesion may influence the extent of remyelination.\(^3\) This is generally the case with a person who is diagnosed with multiple sclerosis early, when they first begin to have symptoms.

### Neuroglial Cells of the Central Nervous System

Neuroglial cells of the CNS consist of the oligodendrocytes, astrocytes, microglia, and ependymal cells (Fig. 17.2). The *oligodendrocytes* form the myelin in the CNS. Instead of forming a myelin covering for a single axon, these cells reach out with several processes, each wrapping around and forming a multilayered myelin segment around several different axons. As with peripheral myelinated fibers, the covering of axons in the CNS increases the velocity of nerve conduction.

*Astrocytes*, the most numerous of neuroglial cells, are particularly prominent in the gray matter of the CNS. These large cells have many processes, some reaching to the surface of the capillaries, others reaching to the surface of the nerve cells, and still others filling most of the intercellular space within the CNS. Astrocytes maintain an important link between neurons, especially between synapses, and capillary blood flow. They also help to maintain the right potassium ion concentration in the extracellular space between neurons. Because astrocytes are highly permeable to potassium, they can take up excess potassium and so protect other neurons. In addition, astrocytes take up neurotransmitters from synaptic zones after their release and thereby help regulate synaptic activity. Research suggests that astrocytes may also play an important role in the regulation of blood flow to the cerebral gray matter.\(^4\) Astrocytes are also the principal cells responsible for repair and scar formation in the brain. They can fill their cytoplasm with microfibrils (*i.e.*, fibrous astrocytes), and
masses of these cells form the special type of scar tissue that develops in the CNS when tissue is destroyed. This process is called gliosis.

A third type of neuroglial cell, the microglia, is a small phagocytic cell that is available for cleaning up debris after cellular damage, infection, or cell death. The fourth type of cell, the ependymal cell, forms the lining of the neural tube cavity, the ventricular system. In some areas, these cells combine with a rich vascular network to form the choroid plexus, where production of the cerebrospinal fluid (CSF) takes place.

**Neuroglial Cells of the Peripheral Nervous System**

Satellite and Schwann cells are the two types of neuroglial cells in the PNS. Normally, the nerve cell bodies in the PNS are collected into ganglia, such as the dorsal root and autonomic ganglia. Satellite cells are flattened capsular cells that secrete a basement membrane that protects the cell body from the diffusion of large molecules. A single layer of satellite cells separates each of the cell bodies, and processes of the peripheral nerves are separated from the connective tissue framework of the ganglion.

Schwann cells are close relatives of the satellite cells. The cell membrane and cytoplasm of Schwann cells surrounds the processes of larger afferent and efferent neurons. During myelination, the Schwann cell wraps around each nerve process several times (Fig. 17.3). Schwann cells line up along the neuronal process, and each of these cells forms its own discrete myelin segment. The end of each myelin segment attaches to

---

**FIGURE 17.2** The supporting cells of the CNS. Diagrammatic view of relationships between the glial elements (astrocyte, oligodendrocyte, microglial cell, and ependymal cells), the capillaries, the CSF, and the cell bodies of CNS neurons.

**FIGURE 17.3** Section of a peripheral nerve containing both afferent (sensory) and efferent (motor) neurons. Schwann cells form a myelin sheath around the larger nerve fibers in the PNS. Successive Schwann cells are separated by short extracellular fluid gaps called the nodes of Ranvier, where the myelin is missing and the voltage-gated sodium channels are concentrated.
the cell membrane of the axon by means of intercellular junctions. Successive Schwann cells are separated by short extracellular fluid gaps, called the **nodes of Ranvier**, where the myelin is missing and voltage-gated sodium channels are concentrated (Fig. 17.4). The nodes of Ranvier increase nerve conduction by allowing the impulse to jump from node to node through the extracellular fluid in a process called **saltatory conduction**. In this way, the impulse can travel more rapidly than it could if it were required to move systematically along the entire nerve process. This increased conduction velocity greatly reduces reaction time, or time between the application of a stimulus and the subsequent motor response. The short reaction time is especially important in peripheral nerves with long distances (sometimes 1 to 1.5 m) for conduction between the CNS and distal effector organs.

Each of the Schwann cells along a peripheral nerve is encased in a continuous tube of basement membrane, which in turn is surrounded by a multilayered sheath of loose connective tissue known as the **endoneurium** (see Fig. 17.3). The endoneurial sheath, which is essential to the regeneration of peripheral nerves, provides a collagenous tube through which a regenerating axon can again reach its former target. The endoneurial sheath does not penetrate the CNS. The absence of the endoneurial sheaths is thought to be a major factor in the limited axonal regeneration of CNS nerves compared with those of the PNS.

The endoneurial sheaths are bundled with blood vessels into small bundles or clusters of nerves called **fascicles**. In the nerve, another protective covering called the perineurium surrounds the fascicles. The heavy protective **epineurial sheath** of the peripheral nerve further surrounds the fascicles. The protective layers that surround the peripheral nerve processes are continuous with the connective tissue capsule of the sensory nerve endings and the connective tissue that surrounds the effector structures, such as the skeletal muscle cell. Centrally, the connective tissue layers continue along the dorsal and ventral roots of the nerve and fuse with the meninges that surround the spinal cord and brain.

**Metabolic Requirements of Nervous Tissue**

Nervous tissue has a high rate of metabolism. The brain receives 15% to 20% (approximately 750 mL/minute) of the total resting cardiac output and consumes 20% of its oxygen.\(^5\) Despite its substantial energy requirements, the brain cannot store oxygen or effectively engage in anaerobic metabolism. An interruption in the blood or oxygen supply to the brain rapidly leads to clinically observable signs and symptoms. Unconsciousness occurs almost simultaneously with cardiac arrest, and the death of brain cells begins within 4 to 6 minutes. Interruption of blood flow also leads to the accumulation of metabolic byproducts that are toxic to neural tissue.

Glucose is the major fuel source for the nervous system, but neurons have no provision for storing glucose. Ketones can provide for limited temporary energy requirements. However, these sources are rapidly depleted. Unlike muscle cells, neurons have no glycogen stores and must rely on glucose from the blood or the glycogen stores of supporting neuroglial cells. People receiving insulin for diabetes may experience signs of neural dysfunction and unconsciousness (i.e., insulin reaction or shock) when blood glucose drops because of insulin excess.

**IN SUMMARY**

Nervous tissue is composed of two types of cells—neurons and neuroglial cells. Neurons are composed of three parts—a cell body, which controls cell activity; the dendrites, which conduct information toward the cell body; and the axon, which carries impulses from the cell body. Axonal transport mechanisms provide the means to convey materials to and from the cell body and axon terminals. The neuroglial cells consist of several types of neuroglial cells in the CNS and...
Schwann and satellite cells of the PNS. Neuroglial cells protect and provide metabolic support for the neurons, help to regulate blood flow, and aid in segregating them into isolated compartments, which is necessary for normal neuronal function. Nervous system function demands a high proportion of metabolic energy. Glucose is the major fuel for the nervous system. The brain constitutes only 2% of body weight, but receives 15% to 20% of the resting cardiac output.

Neurons are characterized by the ability to communicate with other neurons through electrical impulses or action potentials. Neurons transfer information from one location to another via the frequency and pattern of action potentials.

**Action Potentials**

Nerve signals are transmitted by action potentials, which are abrupt, pulsatile changes in the membrane potential that last about 5 msec. The cell membranes of excitable tissue, including those of nerve and muscle cells, contain ion channels that are responsible for generating these action potentials. Voltage-dependent gates, which open and close with change in the membrane potential, guard the membrane ion channels. Separate voltage-gated channels exist for the sodium, potassium, and calcium ions. Each type of ion channel has a characteristic membrane potential that opens and closes its channels. Also present are ligand-gated channels that respond to chemical messengers such as neurotransmitters; mechanically gated channels that respond to physical changes in the cell membrane; and light-gated channels that respond to fluctuations in light levels.

The excitability of neurons can be affected by conditions that alter the resting membrane potential, moving it either closer to or further from the threshold potential. **Hypopolarization** increases the excitability of the postsynaptic neuron by bringing the membrane potential closer to the threshold potential so that a smaller subsequent stimulus is needed to cause the neuron to fire. **Hyperpolarization** brings the membrane potential further from the threshold and has the opposite, inhibitory effect, decreasing the likelihood that an action potential will be generated.

Action potentials can be divided into three phases—the resting or polarized state, depolarization, and repolarization (Fig. 17.5).

**Resting Membrane Potential**

The resting membrane potential (about −70 mV for large nerve fibers) is the undisturbed period of the action potential during which the nerve is not transmitting impulses. During this period the membrane is said to be *polarized* because of the large separation of charge (i.e., positive on the outside and negative on the inside). The resting phase of the membrane potential continues until some event causes the membrane to increase its permeability to sodium. A **threshold potential** (about −55 mV in large nerve fibers) represents the membrane potential at which neurons or other excitable tissues are stimulated to fire. When the threshold potential is reached, the gate-like structures in the ion channels open. Below the threshold potential, these gates remain tightly closed. The gates function on an all-or-none basis. They are either fully open or fully closed. Under ordinary circumstances, the threshold stimulus is sufficient to open many ion channels, triggering massive depolarization of the membrane (the action potential).

**Depolarization**

Depolarization is characterized by the flow of electrically charged ions. During the depolarization phase, the membrane suddenly becomes permeable to sodium ions. The rapid inflow of sodium ions produces local currents that travel through the adjacent cell membrane, causing the sodium channels in this part of the membrane to open. In neurons, sodium ion gates...
remain open for approximately a quarter of a millisecond. During this phase of the action potential, the inner face of the membrane becomes positive (about +30 mV).

**Repolarization**

Repolarization is the phase during which the polarity of the resting membrane potential is reestablished. This is accomplished with closure of the sodium channels and opening of the potassium channels. The outflow of positively charged potassium ions across the cell membrane returns the membrane potential to negativity. The sodium–potassium adenosine triphosphatase (Na+/K+-ATPase) pump gradually reestablishes the resting ionic concentrations on each side of the membrane. Membranes of excitable cells must be sufficiently repolarized before they can be reexcited. During repolarization, the membrane remains refractory until repolarization is approximately one third complete. This period, which lasts 0.4 to 4 msec, is called the absolute refractory period. During one portion of the recovery period, the membrane can be excited, although only by a stronger-than-normal stimulus. This period is called the relative refractory period.

**Synaptic Transmission**

Neurons communicate with each other through structures known as synapses. Two types of synapses are found in the nervous system—electrical and chemical. Electrical synapses permit the passage of current-carrying ions through small openings called gap junctions that penetrate the cell junction of adjoining cells and allow current to travel in either direction. The gap junctions allow an action potential to pass directly and quickly from one neuron to another. They may link neurons having close functional relationships into circuits.

The most common type of synapse is the chemical synapse. Chemical synapses involve special presynaptic and postsynaptic membrane structures, separated by a synaptic cleft. The presynaptic terminal secretes one and often several chemical transmitter molecules. The secreted neurotransmitters diffuse into the synaptic cleft and bind to receptors on the postsynaptic membrane. In contrast to an electrical synapse, a chemical synapse serves as a rectifier, permitting only one-way communication. Chemical synapses are divided into two types—excitatory and inhibitory. In excitatory synapses, binding of the neurotransmitter to the receptor produces depolarization of the postsynaptic membrane. Binding of the neurotransmitter to the receptor in an inhibitory synapse reduces the postsynaptic neuron’s ability to generate an action potential. Most inhibitory neurotransmitters induce hyperpolarization of the postsynaptic membrane by making the membrane more permeable to potassium or chloride, or both.

Chemical synapses are the slowest component in progressive communication through a sequence of neurons, such as in a spinal reflex. In contrast to the conduction of electrical action potentials, each successive event at the chemical synapse—transmitter secretion, diffusion across the synaptic cleft, interaction with postsynaptic receptors, and generation of a subsequent action potential in the postsynaptic neuron—consumes time.

A neuron’s cell body and dendrites are covered by thousands of synapses, any or many of which can be active at any moment. Because of the interaction of this rich synaptic input, each neuron resembles a little integrator in which circuits of many neurons interact with one another. It is the complexity of these interactions and the subtle integrations involved in producing behavioral responses that gives the system its intelligence.

Chemical synapses exhibit several relationships. Axons can synapse with dendrites (axodendritic), with the cell body (axosomatic), or with the axon (axoaxonic). Dendrites can synapse with axons (dendroaxonic), other dendrites (dendrodendritic), or the cell body of other neurons (dendrosomatic). Synapses between the nerve cell body and axons (somatoaxonic synapses) also have been observed. Synapses occurring between the cell body of neighboring neurons (somatosomatic) are uncommon, except between some efferent nuclei. The mechanism of communication between the presynaptic and the postsynaptic neuron is similar in all types of synapses. The action potential sweeps into the axonal terminals of the afferent neuron and triggers the rapid release of neurotransmitter molecules from the axonal, or presynaptic, surface.

**Excitatory and Inhibitory Postsynaptic Potentials**

A neurotransmitter can cause an excitatory or an inhibitory graded potential. When the combination of a neurotransmitter with a receptor site causes partial depolarization of the postsynaptic membrane, it is called an excitatory postsynaptic potential (EPSP). In other synapses, the combination of a transmitter with a receptor site is inhibitory in the sense that it causes the local nerve membrane to become hyperpolarized and less excitable. This is called an inhibitory postsynaptic potential (IPSP).

Action potentials do not begin in the membrane adjacent to the synapse. They begin in the initial segment of the axon, near the axon hillock (see Fig. 17.1), that lies just before the first myelin segment. The initial segment of the axon is more excitable than the rest of the neuron. The local currents resulting from an EPSP (sometimes called a generator potential) are usually insufficient to reach threshold and cause depolarization of the axon’s initial segment. If several EPSPs occur simultaneously, the area of depolarization can become large enough and the currents at the initial segment can become strong enough to exceed the threshold potential and initiate an action potential. This summation of depolarized areas is called spatial summation. EPSPs also can summate and cause an action potential if they occur in rapid succession. This temporal aspect of the occurrence of two or more EPSPs is called temporal summation.

IPSPs also can undergo spatial and temporal summation with each other and with EPSPs, reducing the effectiveness of the latter by a roughly algebraic summation. If the sum of EPSPs and IPSPs keeps the depolarization at the initial segment below threshold levels, no action potential occurs.

Spatial and temporal summation during synaptic activity serves as a sensitive and complicated switch that requires the right combination of incoming activity before the cell can elicit an action potential. The occurrence and frequency of action potentials in axons constitute an all-or-none situation, which varies only as to the presence or absence of such impulses and their frequency.
Neurons communicate with each other through chemical synapses and the use of neurotransmitters. Chemical synapses consist of a presynaptic neuron, a synaptic cleft, and a postsynaptic neuron. The communication process relies on (1) synthesis and release of the neurotransmitter from a presynaptic neuron, (2) binding of the neurotransmitter to receptors in the postsynaptic neuron, and (3) removal of the neurotransmitter from the receptor site.

**Neurotransmitter Synthesis and Release**

Neurotransmitters are synthesized in the presynaptic neuron and then stored in synaptic vesicles. Communication between the two neurons begins with a nerve impulse that stimulates the presynaptic neuron, followed by movement of the synaptic vesicles to the cell membrane and release of neurotransmitter into the synaptic cleft.

**Receptor Binding**

Once released from the presynaptic neuron, the neurotransmitter moves across the synaptic cleft and binds to receptors on the postsynaptic neuron. The action of a neurotransmitter is determined by the type of receptor (excitatory or inhibitory) to which it binds. Binding of a neurotransmitter to a receptor with an excitatory function often results in the opening of an ion channel, such as the sodium channel. Many presynaptic neurons also have receptors to which a neurotransmitter binds. The presynaptic receptors function in a negative feedback manner to inhibit further release of the neurotransmitter.

Continued
**Neurotransmitter Removal**

Precise control of synaptic function relies on the rapid removal of the neurotransmitter from the receptor site. A released neurotransmitter can (1) be taken back up into the neuron in a process called reuptake, (2) diffuse out of the synaptic cleft, or (3) be broken down by enzymes into inactive substances or metabolites. The action of norepinephrine is largely terminated by the reuptake process, in which the neurotransmitter is taken back into the neuron in an unchanged form and reused. Enzymes in the synaptic cleft or in the nerve terminals can also break it down. The neurotransmitter acetylcholine is rapidly broken down by the enzyme acetylcholinesterase.

**Messenger Molecules**

The function of the nervous system relies on chemical messengers. These messengers include the neurotransmitters, neuromodulators, and neurotrophic or nerve growth factors.

**Neurotransmitters**

Neurotransmitters are chemical substances that excite, inhibit, or modify the response of cerebral cells. They include amino acids, neuropeptides, and monoamines. *Amino acids* are the building blocks of proteins and are present in body fluids. The amino acids glutamine, glycine, and gamma-aminobutyric acid (GABA) serve as neurotransmitters at most CNS synapses. GABA mediates most synaptic inhibition in the CNS. *Neuropeptides* are low–molecular-weight molecules that are made up of two or more amino acids. They include substance P and the endorphins and enkephalins, which are involved in pain sensation and perception. A *monoamine* is an amine molecule containing one amino group (NH₂). Serotonin, dopamine, norepinephrine, and epinephrine are monoamines synthesized from amino acids.

The process of neurotransmission involves the synthesis, storage, and release of a neurotransmitter; the reaction of the neurotransmitter with a receptor; and termination of the receptor action. Neurotransmitters are synthesized in the cytoplasm of the axon terminal. The synthesis of transmitters may require one or more enzyme-catalyzed steps (e.g., one for acetylcholine and three for norepinephrine). Neurons are limited as to the type of transmitter they can synthesize by their enzyme systems. After synthesis, the neurotransmitter molecules are stored in the axon terminal in tiny, membrane-bound sacs called *synaptic vesicles*. These vesicles protect the neurotransmitters from enzyme destruction in the nerve terminal. There may be thousands of vesicles in a single terminal, each containing 10,000 to 100,000 transmitter molecules. The arrival of an impulse at a nerve terminal causes the vesicles to move to the cell membrane and release their transmitter molecules into the synaptic space.

Neurotransmitters exert their actions through specific proteins, called *receptors*, embedded in the postsynaptic membrane. These receptors are tailored precisely to match the size and shape of the transmitter. The interaction between a transmitter and receptor results in a specific physiologic response. The action of a transmitter is determined by the type of receptor (excitatory or inhibitory) to which it binds. Acetylcholine is excitatory when it is released at a myoneural junction, and it is inhibitory when it is released at the sinoatrial node in the heart. Receptors are named according to the type of neurotransmitter with which they interact (e.g., a *cholinergic receptor* is a receptor that binds to acetylcholine).

Rapid removal of a transmitter, once it has exerted its effects on the postsynaptic membrane, is necessary to maintain precise control of neural transmission. A released transmitter can undergo one of three processes:

1. It can be broken down into inactive substances by enzymes.
2. It can be taken back up into the presynaptic neuron in a process called reuptake.
3. It can diffuse into the intercellular fluid until its concentration is too low to influence postsynaptic excitability.

An example of these processes is when acetylcholine is rapidly broken down by acetylcholinesterase into acetic acid and choline, with the choline being taken back into the presynaptic neuron for reuse in acetylcholine synthesis. The catecholamines are largely taken back into the neuron in an unchanged form for reuse. Enzymes in the synaptic space or in the nerve terminals also can degrade catecholamines.

**Neuromodulators**

Other classes of messenger molecules, known as neuromodulators, also may be released from axon terminals. Neurmodulator molecules react with presynaptic or postsynaptic receptors to alter the release of, or response to, neurotransmitters. Neuromodulators may act on postsynaptic receptors to produce slower and longer-lasting changes in membrane excitability. This alters the action of the faster-acting neurotransmitter molecules by enhancing or decreasing their effectiveness. By combining with autoreceptors on its own presynaptic membrane, a transmitter can act as a neuromodulator to augment or inhibit further nerve activity. In some nerves, such as the peripheral sympathetic nerves, a messenger molecule can have both transmitter and modulator functions. For example, norepinephrine can activate α₁-adrenergic postsynaptic receptors to produce vasoconstriction or stimulate α₂-adrenergic presynaptic receptors to inhibit further norepinephrine release.

**Neurotrophic Factors**

Neurotrophic or nerve growth factors are required to maintain the long-term survival of the postsynaptic cell and are secreted by axon terminals independent of action potentials. Examples include neuron-to-neuron trophic factors in the sequential synapses of CNS sensory neurons. Trophic factors from target cells that enter the axon and are necessary for the long-term survival of presynaptic neurons also have been demonstrated. Target cell-to-neuron trophic factors probably have great significance in establishing specific neural connections during normal embryonic development.

The organization of the nervous system can be described in terms of its development, in which newer functions and greater complexity resulted from the modification and enlargement of more primitive structures. Thus, the rostral or front end of the CNS became specialized, with the more ancient organization...
being retained in the brain stem and spinal cord. The dominance of the front end of the CNS is reflected in what has been termed a hierarchy of control, with the forebrain having control over the brain stem and the brain stem having control over the spinal cord. In the developmental process, newer functions were added to the surface of functionally older systems. As newer functions became concentrated at the rostral end of the nervous system, they also became more vulnerable to injury. Nothing exemplifies this principle better than the persistent vegetative state. This occurs when severe brain injury causes irreversible damage to higher cortical centers, while lower stem centers such as those that control breathing remain functional.

**Embryonic Development**

All body tissues and organs have developed from the three embryonic layers (i.e., ectoderm, mesoderm, and endoderm) that were present during the 3rd week of embryonic life. The body is organized into the soma and viscera. The soma, or body wall, includes all of the structures derived from the embryonic ectoderm, such as the epidermis of the skin and the CNS. Mesodermal connective tissues of the soma include the dermis of the skin, skeletal muscle, bone, and the outer lining of the body cavity (i.e., parietal pleura and peritoneum). The nervous system innervates all somatic structures plus the internal structures making up the viscera. Viscera include the great vessels derived from the intermediate mesoderm, the urinary system, and the gonadal structures. It also includes the inner lining of the body cavities, such as the visceral pleura and peritoneum, and the mesodermal tissues that surround the endoderm-lined gut and its derivative organs (e.g., lungs, liver, pancreas).

The nervous system appears very early in embryonic development (week 3). This early development is essential because it influences the development and organization of many other body systems, including the axial skeleton, skeletal muscles, and sensory organs such as the eyes and ears. Throughout life, the organization of the nervous system retains many patterns that were established during embryonic life. It is this early pattern of segmental development in the embryo that is presented as a framework for understanding the nervous system.

During the 2nd week of development, embryonic tissue consists of two layers, the endoderm and the ectoderm. At the beginning of week 3, the ectoderm begins to invaginate and migrates between the two layers, forming a third layer called the mesoderm (Fig. 17.6). Mesoderm along the entire midline of the embryo forms a specialized rod of embryonic tissue called the notochord. The notochord and adjacent mesoderm provide the necessary induction signal for the overlying ectoderm to differentiate and form a thickened structure called the neural plate, the primordium of the nervous system. Within the neural plate an axial groove (i.e., neural groove) develops and sinks into the underlying mesoderm, allowing its walls

![FIGURE 17.6 • Folding of the neural tube.](image)
to fuse across the top and form an ectodermal tube called the **neural tube**. This process, called **closure**, occurs during the later 3rd and 4th weeks of gestation and is vital to the survival of the embryo.

During embryonic development, the neural tube develops into the CNS, while the notochord becomes the foundation around which the vertebral column ultimately develops. The surface ectoderm separates from the neural tube and fuses over the top to become the outer layer of skin. Initial closure of the neural tube begins at the cervical and high thoracic levels and zippers rostrally toward the cephalic end of the embryo and caudally toward the sacrum. Complete closure occurs around day 25 at the rostral-most end of the brain (i.e., anterior neuropore) and around day 27 in the lumbosacral region (i.e., posterior neuropore).

As the neural tube closes, ectodermal cells called **neural crest cells** migrate away from the dorsal surface of the neural tube to become the progenitors of the neurons and supporting cells of the PNS. During this period of embryonic development, neural cell adhesive molecules (N-CAMs) are produced to decrease migration of neural crest cells. In addition, fibronectin molecules are produced to increase the formation of pathways that guide the neural crest cells during their migration. Some of these cells gather into clusters to form the **dorsal root ganglia** at the sides of each spinal cord segment and the **cranial ganglia** that are present in most brain segments. Neurons of these ganglia become the afferent or sensory neurons of the PNS. Other neural crest cells become the pigment cells of the skin or contribute to the formation of the meninges, many structures of the face, and the peripheral ganglion cells of the ANS, including those of the adrenal cortex.

During development, the more rostral portions of the embryonic neural tube—approximately 10 segments—undergo extensive modification and enlargement to form the brain (Fig. 17.7). In the early embryo, 3 swellings, or primary vesicles, develop, subdividing these 10 segments into the prosencephalon, or forebrain, containing the first 2 segments; the mesencephalon, or midbrain, which develops from segment 3; and the rhombencephalon, or hindbrain, which develops from segments 4 to 10. The brain stem is formed from modifications of the 10 rostral segments of the wall of the neural tube. In the prosencephalon or forebrain, two pairs of lateral outpouchings develop—the optic cup, which becomes the optic nerve and retina, and the telencephalic vesicles, which become the cerebral hemispheres. Within the prosencephalon, the hollow central canal expands to become enlarged CSF-filled cavities, the first and second (lateral) ventricles. The remaining diencephalic portion of the neural tube develops into the thalamus and hypothalamus. The neurohypophysis (posterior pituitary) grows as a midline ventral outgrowth at the junctions of segments 1 and 2. A dorsal outgrowth, the pineal body, develops between segments 2 and 3.

All brain segments, except segment 2, retain some portion of the basic segmental organization of the nervous system. The evolutionary development of the brain is reflected in the cranial- and upper cervical–paired segmental nerves. This reflects the original pattern of a segmented neural tube, each segment of which has multiple paired branches containing a grouping of component axons. One segment would have paired branches to body muscles and another set to visceral structures, and so on. The classic pattern of spinal nerve organization, which consists of a pair of dorsal and a pair of ventral roots, is a later evolutionary development that has not occurred in the CNs. Consequently, the CNs, which are arbitrarily numbered 1 through 12, retain the ancient pattern, with more than one CN branching from a single segment. The truly segmental nerve pattern of the CNs is altered because all branches from segment 2 and most of the branches from segment 1 are missing. CN II, also called the **optic nerve**, is not a segmental nerve. It is a brain tract connecting the retina (modified brain) with the first forebrain segment from which it developed.

---

**FIGURE 17.7** Frontal and lateral views of a 5-week-old embryo showing the brain vesicles and three embryonic divisions of the brain and brain stem.
Segmental Organization

Developmentally, the basic organizational pattern of the body is that of a longitudinal series of segments, each repeating the same fundamental pattern. Although the early muscular, skeletal, vascular, and excretory systems and the nerves that supply the somatic and visceral structures have the same segmental pattern, it is the nervous system that most clearly retains this organization in postnatal life. The CNS and its associated peripheral nerves consist of approximately 43 segments, 33 of which form the spinal cord and spinal nerves and 10 of which form the brain and its CNs.

Bilateral pairs of bundled nerve fibers, or roots; a ventral pair; and a dorsal pair accompany each segment of the CNS (Fig. 17.8). The paired dorsal roots connect a pair of dorsal root ganglia and their corresponding CNS segment. The dorsal root ganglia contain many afferent nerve cell bodies, each having two axon-like processes—one that ends in a peripheral receptor and the other that enters the central neural segment. These axon-like processes that enter the central neural segment communicate with neurons called input association (IA) neurons. Somatic afferent (SA) neurons transmit information from the soma to somatic IA (SIA) neurons, and visceral afferent (VA) neurons transmit information from the viscera to visceral IA (VIA) neurons. The paired ventral roots of each segment are bundles of axons that provide efferent output to effector sites such as the muscles and glandular cells of the body segment.

On cross section, the hollow embryonic neural tube can be divided into a central canal, or ventricle, containing CSF and the wall of the tube. The latter develops into an inner gray cellular portion, which is functionally divided into longitudinal columns of neurons called the cell columns. These cell columns contain nerve cell bodies surrounded by a superficial white matter region containing the longitudinal tract systems of the CNS. These tract systems are composed of many nerve cell processes. The dorsal half, or dorsal horn of the gray matter, contains afferent neurons. The ventral portion, or ventral horn, contains efferent neurons that communicate by way of the ventral roots with effector cells of the body segment. Many CNS neurons develop axons that grow longitudinally as tract systems that communicate between adjacent and distal segments of the neural tube.

Cell Columns

The organizational structure of the nervous system can be described as a pattern in which functionally specific PNS and CNS neurons are repeated as parallel cell columns running lengthwise along the nervous system. In this pattern, afferent neurons, dorsal horn cells, and ventral horn cells are organized as a bilateral series of 11 cell columns.

The cell columns on each side can be further grouped according to their location in the PNS—four in the dorsal root ganglia that contain sensory neurons, four in the dorsal horn containing sensory IA neurons, and three in the ventral horn that contain motor neurons (Fig. 17.9). Each column of dorsal root ganglia projects to its particular column of IA neurons in the dorsal horn, which then distribute the afferent information to local reflex circuits and to more rostral and elaborate segments of the CNS. The ventral horns contain output association (OA) neurons and lower motor neurons (LMNs). The LMNs provide the final circuitry for organizing efferent nerve activity.

Between the IA neurons and the OA neurons are networks of small internuncial (interneuronal) neurons arranged in complex circuits. Internuncial neurons provide the discreteness, appropriateness, and intelligence of responses to stimuli. Most of the billions of CNS cells in the spinal cord and brain gray matter are internuncial neurons.
FIGURE 17.9 • (A) Cell columns of the CNS. The cell columns in the dorsal horn contain input association (IA) neurons for the general visceral afferent (GVA), special visceral afferent (SVA), special sensory afferent (SSA), and general somatic afferent (GSA) neurons with cell bodies in the dorsal root ganglion. The cell columns in the ventral horn contain the general visceral efferent (GVE), pharyngeal efferent (PE), and general somite efferent (GSE) neurons and their OA neurons. (B) Schematic of the GVE cell column showing both parasympathetic and sympathetic components. The column is not continuous but is interrupted in the brain stem because only the nuclei of CNs III, VII, IX, and X contain preganglionic parasympathetic neurons. The column again is interrupted until levels T1 to L1 or L2, where the preganglionic neurons of the sympathetic portion are found in the lateral horn of the spinal cord. Another gap is evident until the sacral portion of the parasympathetic nervous system.

Dorsal Horn Cell Columns. Four columns of afferent (sensory) neurons in the dorsal root ganglia directly innervate four corresponding columns of IA neurons in the dorsal horn. These columns are categorized as special and general afferents: special SA, general SA, special VA, and general VA (see Fig. 17.9).

Special somatic afferent fibers are concerned with internal sensory information such as joint and tendon sensation (i.e., proprioception). Neurons in the special SIA column cells relay their information to local reflexes concerned with posture and movement. These neurons also relay information to the cerebellum, contributing to coordination of movement, and to the forebrain, contributing to experience. Afferents innervating the labyrinth and derived auditory end organs of the inner ear also belong to the special SA category.

General somatic afferents innervate the skin and other somatic structures and respond to stimuli such as those that produce pressure or pain. General SIA column cells relay the sensory information to protective and other reflex circuits and project the information to the forebrain, where it is perceived as painful, warm, cold, and the like.

Special visceral afferent cells innervate specialized gut-related receptors, such as the taste buds and receptors of the olfactory mucosa. Their central processes communicate with special VIA column neurons that project to reflex circuits producing salivation, chewing, swallowing, and other responses. Forebrain projection fibers from these association cells provide sensations of taste and smell.

General visceral afferent neurons innervate visceral structures such as the gastrointestinal tract, urinary bladder, and heart and great vessels. They project to the general VIA column, which relays information to vital reflex circuits and sends information to the forebrain regarding visceral sensations such as stomach fullness, bladder pressure, and sexual experience.

Ventral Horn Cell Columns. The ventral horn contains three longitudinal cell columns—general visceral efferent, pharyngeal efferent, and general somatic efferent (see Fig. 17.9). Each of these cell columns contains OA and efferent neurons. The OA neurons coordinate and integrate the function of the efferent motor neurons cells of their column.

General visceral efferent neurons transmit the efferent output of the ANS and are called preganglionic neurons. These neurons are structurally and functionally divided into either the sympathetic or the parasympathetic nervous systems. Their axons project through the segmental ventral roots (specifically from a group of neurons originating in the intermediolateral horn of the thoracolumbar cord) to innervate smooth and cardiac muscle and glandular cells of the body, most of which are in the viscera. In the viscera, three additional neural crest–derived cell columns are present on each side of the body. These become the postganglionic neurons of the ANS. In the sympathetic nervous system, the paravertebral ganglia (sympathetic chain) and the prevertebral series of ganglia (e.g., celiac ganglia) associated with the dorsal aorta represent the columns. For the parasympathetic system, these become the enteric plexus in the wall of the gut-derived organs and a series of ganglia in the head. This column is not continuous but is interrupted in the brain stem because only
the nuclei for CNs III, VII, IX, and X contain preganglionic parasympathetic neurons. The column is again interrupted until thoracic (T) levels T1 to lumbar (L) levels L1 or L2, where the preganglionic neurons of the sympathetic nervous system are found in the lateral horn of the spinal cord. Another gap is evident until the sacral portion of the parasympathetic nervous system.

Pharyngeal efferent neurons innervate branchial arch skeletal muscles—the muscles of mastication and facial expression and muscles of the pharynx and larynx. Pharyngeal efferent neurons also innervate muscles responsible for moving the head.

The general somatic efferent neurons supply somite-derived muscles of the body and head, which include the skeletal muscles of the body and limbs, the tongue, and the extrinsic eye muscles. These efferent neurons transmit the commands of the CNS to peripheral effectors, the skeletal muscles. They are the “final common pathway neurons” in the sequence leading to motor activity. They are often called lower motor neurons (LMNs) because they are under the control of higher levels of the CNS. LMNs have their cell bodies in the brain stem and spinal cord.

Peripheral Nerves. Peripheral nerves, including cranial and spinal nerves, contain afferent and efferent processes of more than one of the four afferent and three efferent cell columns. This provides the basis for assessing the function of any peripheral nerve. The functional components of each of the cranial and spinal nerves are presented in Table 17.1.

Longitudinal Tracts

The gray matter of the cell columns in the CNS is surrounded by bundles of myelinated axons (i.e., white matter) and unmyelinated axons that travel longitudinally along the length of the neural axis. This white matter can be divided into three layers—an inner, middle, and outer layer (Fig. 17.10). The inner layer, or archilayer, contains short fibers that project for a maximum of approximately five segments before reentering the gray matter. The middle layer, or paleolayer, projects to six or more segments. Archilayer and paleolayer fibers have many branches, or collaterals, that enter the gray matter of intervening segments. In the outer layer, or neolayer, are found large-diameter axons that can travel the entire length of the nervous system (Table 17.2). Suprasegmental is a term that refers to higher levels of the CNS, such as the brain stem and cerebrum and structures above a given CNS segment. Paleolayer and neolayer fibers have suprasegmental projections.

The longitudinal layers are arranged in bundles, or fiber tracts, that contain axons that have the same destination, origin, and function (Fig. 17.11). These longitudinal tracts are named systematically to reflect their origin and destination; the origin is named first, and the destination is named second. For example, the spinothalamic tract originates in the spinal cord and terminates in the thalamus. The corticospinal tract originates in the cerebral cortex and ends in the spinal cord.

The Inner Layer. Lying deep to the superficial gray matter, the inner layer of white matter contains the axons of neurons that connect neighboring segments of the nervous system. Axons of this layer permit motor neurons of several segments to work together as a functional unit. They also allow the afferent neurons of one segment to trigger reflexes that activate motor units in neighboring segments as well as in the same one. From the standpoint of evolutionary development, this is the oldest of the three layers, and it is sometimes called the archilayer. It is the first of the longitudinal layers to become functional, and its circuitry may be limited to reflex types of movements, including reflex movements of the fetus (i.e., quickening) that begin during the 5th month of intrauterine life.

The inner layer of the white matter differs from the other two layers in one important aspect. Many neurons in the embryonic gray matter migrate out into this layer, resulting in a rich mixture of neurons and local fibers called the reticular formation. The circuitry of most reflexes is contained in the reticular formation. In the brain stem, the reticular formation becomes quite large and contains major portions of vital reflexes, such as those controlling respiration, cardiovascular function, swallowing, and vomiting. A functional system called the reticular activating system operates in the lateral portions of the reticular formation of the medulla, pons, and especially the midbrain. Information derived from all sensory modalities, including those of the somesthetic, auditory, visual, and VA nerves, bombards the neurons of this system.

The reticular activating system has descending and ascending portions. The descending portion communicates with all spinal segmental levels through paleolayer reticulo-spinal tracts and serves to facilitate many cord-level reflexes. For example, it speeds reaction time and stabilizes postural reflexes. The ascending portion accelerates brain activity, particularly thalamic and cortical activity. This is reflected by the appearance of awake-type patterns of brain wave activity. Sudden stimuli result in protective and attentive postures and increased awareness.

The Middle Layer. The middle layer of the white matter contains most of the major fiber tract systems required for sensation and movement, including the ascending spinoreticular and spinothalamic tracts. This layer consists of larger-diameter and longer suprasegmental fibers, which ascend to the brain stem and are largely functional at birth. These tracts are quite old from an evolutionary standpoint, and, as such, this layer is sometimes called the paleolayer. It facilitates many primitive functions, such as the auditory startle reflex, which occurs in response to loud noises. This reflex consists of turning the head and body toward the sound, dilation of the pupils of the eyes, catching of the breath, and quickening of the pulse.

The Outer Layer. The outer layer of the tract systems is the newest of the three layers with respect to evolutionary development, and it is sometimes called the neolayer. It becomes functional approximately the 2nd year of life, and it includes

Afferent (sensory) components: SSA, special somatic afferent; GSA, general somatic afferent; SVA, special visceral afferent; GVA, general visceral afferent.

Efferent (motor) components: GVE, general visceral efferent (autonomic nervous system); PE, pharyngeal efferent; GSE, general somatic efferent; DTRs, deep tendon reflexes.

Figure 17.10 • The three concentric subdivisions of the tract systems of the white matter. Migration of neurons into the archilayer converts it into the reticular formation of the white matter.

The pathways needed for bladder training. Myelination of these suprasegmental tracts, which include many pathways required for delicate and highly coordinated skills, is not complete until approximately the 5th year of life. This includes the development of tracts needed for fine manipulative skills, such as the finger–thumb coordination required for using tools and the toe movements needed for acrobatics. Neolayer tracts are the most recently evolved systems and, because they are situated more superficially on the brain and spinal cord, are the most vulnerable to injury. When neolayer tracts are damaged, the paleolayer and archilayer tracts often remain functional, and rehabilitation methods can result in effective use of the older systems. Delicacy and refinement may be lost, but basic function remains. For example, when the corticospinal system, an important neolayer system that permits the fine manipulative control required for writing, is damaged, the remaining paleolayer systems, if intact, permit the grasping and holding of objects. The hand can still be used to perform basic functions, but the fine manipulative functions of the fingers are lost.

**Collateral Communication Pathways.** Axons in the archilayer and paleolayer characteristically possess many collateral branches that move into the gray cell columns or synapse with fibers of the reticular formation as the axon passes each succeeding CNS segment. Should a major axon be destroyed at some point along its course, these collaterals provide multisynaptic alternative pathways that bypass the local damage. Neolayer tracts do not possess these collaterals but instead project mainly to the target neurons with which they communicate. Because of this, damage to the neolayer tracts causes permanent loss of function. Damage to the archilayer or paleolayer systems is usually followed by a slow return of function, presumably through the collateral connections.

**IN SUMMARY**

The CNS develops from the ectoderm of the early embryo by formation of a hollow tube that closes along its longitudinal axis and sinks below the surface. This hollow tube forms the ventricles of the brain and spinal canal, and the sidewall develops to form the brain stem and spinal cord. Development of the CNS requires the coordinated production of many embryonic inductive factors. The brain stem and spinal cord are subdivided into the dorsal horn, which contains neurons that receive and process incoming or afferent sensory information, and the ventral horn, which contains efferent motor neurons that handle the final stages of output processing. The PNS develops from ectodermal cells called *neural crest cells* that migrate away from the dorsal surface of the forming neural tube.

Throughout life, the organization of the nervous system retains many patterns established during early embryonic life. This segmental pattern of early embryonic development is retained in the fully developed nervous system. Each of the 43 or more body segments is connected to corresponding CNS or neural tube segments by segmental afferent and efferent neurons. Afferent neuronal processes enter the CNS through the dorsal root ganglia and the dorsal roots. Afferent neurons of the dorsal root ganglia are of four types: general SA, special SA, general VA, and special VA. Each of these afferent neurons synapses with its appropriate IA neurons in the cell columns of the dorsal horn (e.g., general SAs synapse with neurons in the general...
SA IA cell column). Efferent fibers from motor neurons in the ventral horn exit the CNS in the ventral roots. General somatic efferent neurons are LMNs that innervate somite-derived skeletal muscles, and general visceral efferent neurons are preganglionic fibers that synapse with postganglionic fibers that innervate visceral structures. This pattern of afferent and efferent neurons, which is usually repeated in each segment of the body, forms parallel cell columns running lengthwise through the CNS and PNS.

Longitudinal communication between CNS segments is provided by neurons that send the axons into nearby segments by means of the innermost layer of the white matter, the ancient archilayer system of fibers. These cells provide coordination between adjacent segments. Neurons have invaded this layer, and the mix of these cells and axons is called the reticular formation. The reticular formation is the location of many important reflex circuits of the spinal cord and brain stem. Paleolayer tracts, located outside the archilayer, provide the longitudinal communication between more distant segments of the nervous system. This layer includes most of the important ascending and descending tracts. The recently evolved neolayer systems, which become functional during infancy and childhood, travel outside the white matter and provide the means for very delicate and discriminative function. The outer position of the neolayer tracts and their lack of collateral and redundant pathways make them the most vulnerable to injury.

**STRUCTURE AND FUNCTION OF THE SPINAL CORD AND BRAIN**

After completing this chapter, you should be able to meet the following objectives:

- Describe the innervation and function of spinal cord reflexes.
- Identify the structures of the hindbrain, midbrain, and forebrain, and describe their functions.
- Identify the cranial nerves, and describe their location and function.

**Spinal Cord**

In the adult, the spinal cord is found in the upper two thirds of the spinal canal of the vertebral column (Fig. 17.12). It extends from the foramen magnum at the base of the skull to a cone-shaped termination, the conus medullaris, usually at the level of the first or second lumbar vertebra (L1 or L2) in the adult. Consequently, the dorsal and ventral roots of the more caudal portions of the cord elongate during development and angle downward from the cord, forming what is called the cauda equina (from the Latin for “horse’s tail”). The filum terminale, which is composed of nonneural tissues and the pia mater, continues caudally and attaches to the second sacral vertebra (S2).

The spinal cord is somewhat oval on transverse section. Internally, the gray matter has the appearance of a butterfly or the letter “H” on cross section (see Fig. 17.12). Some neurons that make up the gray matter of the cord have processes or axons that leave the cord, enter the peripheral nerves, and supply tissues such as autonomic ganglia or skeletal muscles. The white matter of the cord that surrounds the gray matter contains nerve fiber tracts of ascending and descending axons that transmit information between segments of the cord or from higher levels of the CNS, such as the brain stem or cerebrum.

Internally, the extensions of the gray matter that form the letter “H” are called the horns. Those that extend posteriorly are called the dorsal horns, and those that extend anteriorly are called the ventral horns. Dorsal horns contain IA neurons that receive afferent impulses through the dorsal roots and other connecting neurons. Ventral horns contain OA neurons and the efferent LMNs that leave the cord through the ventral roots. The central portion of the cord, which connects the dorsal and ventral horns, is called the intermediate gray matter. The intermediate gray matter surrounds the central canal. In the thoracic area, the small, slender projections that emerge from the intermediate gray matter are called the intermediolateral columns of the horns. These columns contain the visceral OA neurons and the efferent neurons of the sympathetic nervous system.

The amount of gray matter is proportional to how much tissue is innervated by a given segment of the cord (see Fig. 17.12). Larger amounts of gray matter are present in the lower lumbar and upper sacral segments, which supply the lower extremities, and in the fifth cervical segment to the first thoracic segment, which supply the upper limbs. The white matter in the spinal cord also increases progressively toward the brain because ever more ascending fibers are added and the number of descending axons is greater.

The spinal cord and the dorsal and ventral roots are covered by a connective tissue sheath, the pia mater, which also contains the blood vessels that supply the white and gray matter of the cord (Fig. 17.13). On the lateral sides of the spinal cord, extensions of the pia mater, the denticulate ligaments, attach the sides of the spinal cord to the bony walls of the spinal canal. Thus, the cord is suspended by both the denticulate ligaments and the segmental nerves. A fat- and vessel-filled epidural space intervenes between the spinal dura mater and the inner wall of the spinal canal.

The spinal cord and nerves and their supporting structures are protected by the vertebral column. The vertebral body is the anterior, more massive part of the bone that gives strength to the vertebral column and supports body weight. Each vertebral body has two pedicles that extend posteriorly and support the laterally oriented transverse processes of the laminae, which arch medially and fuse to continue as the spinal processes. The vertebral arch and posterior surface of the vertebral body form the wall of the vertebral foramen. The succession of vertebral foramina in the articulated spinal column forms the vertebral canal (spinal canal), which contains

Fig. 17.12). Larger amounts of gray matter are present in the lower lumbar and upper sacral segments, which supply the lower extremities, and in the fifth cervical segment to the first thoracic segment, which supply the upper limbs. The white matter in the spinal cord also increases progressively toward the brain because ever more ascending fibers are added and the number of descending axons is greater.

The spinal cord and the dorsal and ventral roots are covered by a connective tissue sheath, the pia mater, which also contains the blood vessels that supply the white and gray matter of the cord (Fig. 17.13). On the lateral sides of the spinal cord, extensions of the pia mater, the denticulate ligaments, attach the sides of the spinal cord to the bony walls of the spinal canal. Thus, the cord is suspended by both the denticulate ligaments and the segmental nerves. A fat- and vessel-filled epidural space intervenes between the spinal dura mater and the inner wall of the spinal canal.

The spinal cord and nerves and their supporting structures are protected by the vertebral column. The vertebral body is the anterior, more massive part of the bone that gives strength to the vertebral column and supports body weight. Each vertebral body has two pedicles that extend posteriorly and support the laterally oriented transverse processes of the laminae, which arch medially and fuse to continue as the spinal processes. The vertebral arch and posterior surface of the vertebral body form the wall of the vertebral foramen. The succession of vertebral foramina in the articulated spinal column forms the vertebral canal (spinal canal), which contains
the spinal cord, meninges, fat, and spinal nerve roots. The spaces between the vertebral bodies are filled with fibrocartilaginous disks and stabilized with tough ligaments. A gap, the intervertebral foramen, occurs between each two succeeding pedicles, allowing for the exit of the segmental nerves and passage of blood vessels.

Early in fetal life, the spinal cord extends the entire length of the vertebral column, and the spinal nerves exit through the intervertebral foramina (openings) near their level of origin. Because the vertebral column and spinal dura grow faster than the spinal cord, a disparity develops between each succeeding cord segment and the exit of its dorsal and ventral nerve roots through the corresponding intervertebral foramina. In the newborn, the cord terminates at vertebral level L2 or L3, whereas the adult cord usually terminates at the inferior border of L1. In addition, the arachnoid and its enclosed subarachnoid space, which is filled with CSF, do not close down on the filum terminale until they reach the second sacral vertebra. This results in the formation of a pocket of CSF, the dural cisterna spinalis, which extends from approximately L2 to S2. Because this area contains an abundant supply of CSF

**FIGURE 17.12**  • (A) Posterior view of the spinal cord, including portions of the major spinal nerves and some of the components of the major nerve plexuses. (B) Cross-sectional views of the spinal cord, showing regional variations in gray matter and increasing white matter as the cord ascends.

and the spinal cord does not extend this far, the area (L3 or L4) is often used to perform a lumbar puncture and obtain a CSF sample. The spinal roots are in little danger of trauma from the spinal needle used in this procedure.

**Spinal Nerves**

The peripheral nerves that carry information to and from the spinal cord are called **spinal nerves**. Thirty-one pairs of spinal nerves are present (i.e., 8 cervical, 12 thoracic, 5 lumbar, 5 sacral, and 1 coccygeal). Each pair is named for the segment of the spinal cord from which it exits. Because the first cervical spinal nerve exits the spinal cord just above the first cervical vertebra (C1), the nerve is given the number of the bony vertebra just below it. The numbering is changed for all lower levels, however. Cervical nerve 8 (C8) exits above the T1 vertebra, and each subsequent nerve is numbered for the vertebra just above its point of exit (see Fig. 17.12).

Each spinal cord segment communicates with its corresponding body segment through the paired segmental spinal nerves (see Fig. 17.8). Each spinal nerve, accompanied by the blood vessels supplying the spinal cord, enters the spinal canal through an intervertebral foramen, where it divides into two branches, or roots. One branch enters the dorsolateral surface of the cord (i.e., dorsal root), carrying the axons of afferent neurons into the CNS. The other branch leaves the ventrolateral surface of the cord (i.e., ventral root), carrying the axons of efferent neurons into the periphery. These two branches or roots fuse at the intervertebral foramen, forming the mixed spinal nerve—“mixed” because it has both afferent and efferent axons.

After emerging from the vertebral column, the spinal nerve divides into two branches or **rami** (singular, **ramus**)—a small dorsal primary ramus and a larger ventral primary ramus (Fig. 17.14). Thoracic and upper lumbar spinal nerves also produce a third branch, the **ramus communicans**, which contains sympathetic axons supplying the blood vessels, the genitourinary system, and the gastrointestinal system. The dorsal primary ramus contains sensory fibers from the skin and motor fibers to muscles of the back. The ventral primary ramus contains motor fibers that innervate the skeletal muscles of the anterior body wall and the legs and arms.

Spinal nerves do not go directly to skin and muscle fibers; instead, they form complicated nerve networks called **plexuses** (see Fig. 17.11). A plexus is a site of intermixing nerve branches. Many spinal nerves enter a plexus and connect with other spinal nerves before exiting from the plexus. Nerves emerging from a plexus form progressively smaller branches that supply the skin and muscles of the various parts of the body. The PNS contains four major plexuses: the cervical plexus, the brachial plexus, the lumbar plexus, and the sacral plexus.

**Spinal Reflexes**

A reflex is a response between a stimulus and an elicited motor response. Its anatomic basis consists of an afferent (sensory) neuron, the connection within the CNS interneurons that communicate with the effector (motor) neuron, and the effector (motor) neuron that innervates a muscle or organ. A reflex may involve neurons in a single cord segment (i.e., segmental reflexes), several or many segments (i.e., intersegmental reflexes), or structures in the brain (i.e., suprasegmental reflexes). Two important types of spinal motor reflexes are the withdrawal reflex and myotatic reflex.

The withdrawal reflex is stimulated by a damaging (nociceptive) stimulus and quickly moves the body part away from the offending stimulus, usually by flexing a limb part (Fig. 17.15). The withdrawal reflex is a powerful reflex, taking precedence over other reflexes associated with locomotion. Any of the major joints may be involved, depending on the site of afferent stimulation. All the joints of an extremity (e.g., finger, wrist, elbow, shoulder) typically are involved. This complex, polysynaptic reflex also shifts postural support to the opposite side of the body with a crossed extensor reflex and simultaneously alerts the forebrain to the offending stimulus event. The withdrawal reflex also can produce contraction of muscles other than the extremities. For example, irritation of the abdominal viscera may cause contraction of the abdominal muscles.

The myotatic or stretch reflex controls muscle tone and helps maintain posture. Specialized sensory nerve terminals in skeletal muscles and tendons relay information on muscle stretch and joint tension to the CNS. This information, which drives postural reflex mechanisms, also is relayed to the thalamus and the sensory cortex and is experienced as **proprioception**, the sense of body movement and position. To provide this information, the muscles and their tendons are supplied with two types of sensory receptors—muscle spindle receptors and Golgi tendon organs. **Muscle spindles** are stretch receptors distributed throughout the belly of a muscle that transmit information about muscle length and rate of stretch. The **Golgi tendon organs** are found in muscle tendons and transmit information about muscle tension or force of contraction at the...
The hindbrain consists of the metencephalon (cerebellum and pons) and the myelencephalon (medulla oblongata). Sleep disorders and cerebrovascular accidents (CVAs) are disorders that frequently affect the hindbrain. This area of the brain assists in managing motor activity, posture, and major functions such as respiration and circulation of blood.

Medulla. The medulla oblongata represents the caudal five segments of the brain part of the neural tube. The CN branches entering and leaving it have functions similar to the spinal segmental nerves. Although the ventral horn areas in the medulla are quite small, the dorsal horn areas are enlarged, processing a large amount of the information pouring through the CNs. The segmental peripheral nerve components of the medulla can be divided into those leaving the neural tube ventromedially (i.e., hypoglossal CN) or dorsolaterally (i.e., vagus, spinal accessory, glossopharyngeal, and vestibulocochlear CNs). Because pathologic signs and symptoms reflect the spatial segregation of brain stem components, neurologic syndromes resulting from trauma, tumors, aneurysms, and CVAs are often classified as ventral or dorsolateral syndromes.

The general somatic efferent LMNs of the lower segments of the medulla supply the extrinsic and intrinsic muscles of the tongue by means of the hypoglossal nerve (CN XII). Damage to the hypoglossal nerve results in weakness or paralysis of tongue muscles. When the tongue is protruded, it deviates toward the damaged and therefore weaker side because of the greater protrusion strength on the normal side. Axons of the hypoglossal nerve exit the medulla adjacent to the junction of the muscle and the tendon that attaches to bone. A likely role of the tendon organs is to equalize the contractile forces of the separate muscle groups, spreading the load over all the fibers to prevent the local muscle damage that might occur when small numbers of fibers are overloaded.

Hindbrain

The hindbrain consists of the cerebellum and pons and the myelencephalon (medulla oblongata). Sleep disorders and cerebrovascular accidents (CVAs) are disorders that frequently affect the hindbrain. This area of the brain assists in managing motor activity, posture, and major functions such as respiration and circulation of blood.
The sternocleidomastoid, a powerful head-turning muscle, and the trapezius muscle, which elevates the shoulders, are innervated by the spinal accessory nerve (CN XI), with LMNs in the upper four cervical spinal segments. Intermediate rootlets from these segmental levels combine and enter the cranial cavity through the foramen magnum and exit the jugular foramen with CNs IX and X. Loss of spinal accessory nerve function results in drooping of the shoulder on the damaged side and weakness when turning the head to the opposite side.

The dorsolateral glossopharyngeal nerve (CN IX) contains the same components as the vagus nerve but for a more rostral segment of the gastrointestinal tract and the pharynx. This nerve provides the special visceral sensory innervation of the taste buds of the oral pharynx and the back of the tongue; the afferent innervation of the oral pharynx and the baroreceptors of the carotid sinus; the efferent innervation of the otic ganglion, which controls the salivary function of the parotid gland; and the efferent innervation of the stylopharyngeus muscles of the pharynx. This CN is seldom damaged, but when it is, anesthesia of the ipsilateral oral pharynx develops along with dry mouth resulting from reduced salivation.

The special sensory afferent vestibulocochlear nerve (CN VIII), formerly called the auditory nerve, is attached laterally at the junction of the medulla oblongata and the pons, often called the caudal pons. It consists of two distinct fiber divisions, the cochlear and vestibular divisions, both of which are sensory. Cell bodies in the cochlea of the inner ear produce fibers of the cochlear division. These fibers transmit impulses two long, longitudinal ridges along the medial undersurface of the medulla. These ridges, called the pyramids, contain the corticospinal fibers, most of which cross to descend in the lateral column to the opposite side of the spinal cord. Lesions of the ventral surface of the caudal medulla result in the syndrome of alternating hypoglossal hemiplegia. These lesions are characterized by signs of ipsilateral (i.e., same side) denervation of the tongue and contralateral (i.e., opposite side) weakness or paralysis of both the upper and lower extremities.

The vagus nerve (CN X) has several afferent (sensory) and efferent (motor) components. General SA neurons innervate the external ear, whereas special VA neurons innervate the pharyngeal taste buds. Sensory and motor components of the nerve innervate the pharynx, the gastrointestinal tract (from the laryngeal pharynx to the midtransverse colon), the heart, the spleen, and the lungs. Initiation of many essential reflexes and normal functions depends on intact vagal innervation. For example, 80% of the fibers of the vagus nerve are afferent, some of which are involved in vomiting and hiccup reflexes and in ongoing feedback during swallowing and speech. The unilateral loss of vagal function can result in slowed gastrointestinal motility, a permanently husky voice, and deviation of the uvula away from the damaged side. Bilateral loss of vagal function can seriously damage reflex maintenance of cardiovascular and respiratory reflexes. Swallowing may become difficult and, occasionally, paralysis of laryngeal structures causes life-threatening airway obstruction.
related to the sense of hearing. The vestibular division arises from two ganglia that innervate cell bodies in the utricle, saccule, and semicircular canals and transmit impulses related to head position and movement of the body through space. Irritation of the cochlear division results in tinnitus (i.e., ringing of the ears); destruction of the nerve results in nerve deafness. Injury to the vestibular division leads to vertigo, nystagmus, and some postural instability.

The facial nerve (CN VII) and its intermediate component (the intermedius) is a mixed nerve that has both afferent and efferent components. It emerges from the junction of the pons and medulla. The nervus intermedius, containing the general SA, special VA, general VA, and general visceral efferent neurons, innervates the nasopharynx and taste buds of the palate. It also innervates the anterior two thirds of the tongue, the submandibular and sublingual salivary glands, the lacrimal glands, and the mucous membranes of the nose and roof of the mouth. Loss of this branch of the facial nerve can lead to eye dryness with risk of corneal scarring and blindness. The pharyngeal efferent LMNs of the facial nerve proper innervate muscles that control facial expression, such as wrinkling of the brow and smiling. Unilateral loss of facial nerve function results in flaccid paralysis of the muscles of half the face, a condition called Bell palsy.

Pons. The pons (from the Latin for “bridge”) develops from the fifth neural tube segment. Internally, the central canal of the spinal canal, which is enlarged in the pons and rostral medulla, forms the fourth ventricle (see Fig. 17.16B). An enlarged area on the ventral surface of the pons contains the pontine nuclei, which receive information from all parts of the cerebral cortex. Axons of these neurons form a massive bundle that swings around the lateral side of the fourth ventricle to enter the cerebellum. In the pons, the reticular formation is large and contains the circuitry for masticating food and manipulating the jaws during speech.

The abducens nerve (CN VI), which arises from the caudal pons, sends LMNs out ventrally on either side of the pyramids and then forward into the orbit to innervate the lateral rectus muscle of the eye. As the name suggests, the abducens nerve abducts the eye (lateral or outward rotation); peripheral damage to this nerve results in medial strabismus, which is a weakness or loss of eye abduction.

The trigeminal nerve (CN V), which has both sensory and motor subdivisions, exits the brain stem laterally on the forward surface of the pons. The trigeminal is the main sensory nerve conveying the modalities of pain, temperature, touch, and proprioception to the superficial and deep regions of the face. Regions innervated include the skin of the anterior scalp and face, the conjunctiva and orbit, the meninges, the paranasal sinuses, and the mouth, including the teeth and the anterior two thirds of the tongue. LMNs of the trigeminal nerve innervate skeletal muscles involved with mastication and contribute to swallowing and speech, movements of the soft palate, and tension of the tympanic membrane through the tensor tympani muscle. The tensor tympani muscle has a protective reflex function, dampening movement of the middle ear ossicles during high-intensity sound.

Cerebellum. The cerebellum is located in the posterior fossa of the cranium superior to the pons (see Fig. 17.16A). It is separated from the cerebral hemispheres by a fold of dura mater, the tentorium cerebelli. The cerebellum consists of a small, unpaired median portion, called the vermis, and two large lateral masses, the cerebellar hemispheres. In contrast to the brain stem with its external white matter and internal gray nuclei, the cerebellum, like the cerebrum, has an outer cortex of gray matter overlying the white matter. Next to the fourth ventricle, several masses of gray matter, called the deep cerebellar nuclei, border the roof of the fourth ventricle. Cells of the cerebellar cortex and deep nuclei interact, and axons from the latter send information to many regions, particularly to the motor cortex by means of a thalamic relay. Synergistic functions of the cerebellum (i.e., temporal and spatial smoothing) contribute to all movements of the limbs, trunk, head, larynx, and eyes, whether the movement is part of a voluntary movement or of a highly learned semiautomatic or automatic movement. During highly skilled movements, the motor cortex sends signals to the cerebellum, informing it about the movement that is to be performed. The cerebellum makes continuous adjustments, resulting in smoothness of movement, particularly during delicate maneuvers. Highly skillful movement requires extensive motor training, and considerable evidence suggests many of these learned movement patterns involve cerebellar circuits.

The cerebellum receives proprioceptor input from the vestibular system; feedback from the muscles, tendons, and joints; and indirect signals from the somesthetic, visual, and auditory systems that provide background information for ongoing movement. Sensory and motor information from a given area of the body is sent to the same area in the cerebellum. In this way, the cerebellum can assess continuously the status of each body part—position, rate of movement, and forces such as gravity that are opposing movement. The cerebellum compares what is actually happening with what is intended to happen. It then transmits the appropriate corrective signals back to the motor system, instructing it to increase or decrease the activity of the participating muscle groups so that smooth and accurate movements can be performed.

Another function of the cerebellum is the dampening of muscle movement. All body movements are essentially pendular (i.e., swinging back and forth). As movement begins, momentum develops and must be overcome before the movement can be stopped. This momentum would cause movements to overshoot if they were not dampened. In the intact cerebellum, automatic signals stop movement precisely at the intended point. The cerebellum analyzes proprioceptive information to predict the future position of moving parts, their rapidity of movement, and the projected time course of the movement. This allows the cerebellum to inhibit agonist muscles and excite antagonist muscles when movement approaches the intended target.
Midbrain
The midbrain develops from the fourth segment of the neural tube, and its organization is similar to that of a spinal segment. Internally, the central canal is reestablished as the cerebral aqueduct, connecting the fourth ventricle with the third ventricle (see Fig. 17.16B). Two general somatic efferent CNs, the oculomotor nerve (CN III) and the trochlear nerve (CN IV), exit the midbrain.

Two prominent bundles of nerve fibers, the cerebral peduncles, pass along the ventral surface of the midbrain. These fibers include the corticospinal tracts and are the main motor pathways between the forebrain and the pons. On the dorsal surface, four “little hills,” the superior and inferior colliculi, are areas of cortical formation. The inferior colliculi are involved in directional turning and, to some extent, in experiencing the direction of sound sources, whereas the superior colliculi are essential to the reflex mechanisms that control conjugate eye movements when the visual environment is surveyed.

The ventral central gray matter (i.e., ventral horn) of the midbrain contains the LMNs that innervate most of the skeletal muscles that move the optic globe and raise the eyelids. These axons leave the midbrain through the oculomotor nerve (CN III). This nerve also contains the parasympathetic LMNs that control pupillary constriction and ciliary muscle focusing of the lens (see Table 17.1). Damage to the ventrally exiting CN III and to the adjacent cerebral peduncle, which contains the corticospinal axon system on one side, results in paralysis of eye movement combined with contralateral hemiplegia.

A small group of cells in the ventral part of the caudal central gray matter contains the trochlear nerve (CN IV), which innervates the superior oblique eye muscle. This muscle moves the upper part of the eye downward and toward the nose when the eye is adducted, or turned inward. The trochlear nerve exits the dorsal surface of the midbrain and decussates (crosses over) before exiting the brain stem. Lesions of the trochlear nerve affect downward gaze on the side opposite the denervated muscle, producing diplopia, or double vision. Walking downstairs becomes particularly difficult. Because the superior oblique muscle has inward rotation of the optic globe as its major function, persons with trochlear nerve damage usually carry their heads tilted to the side of damage.

Forebrain
The most rostral part of the brain, the forebrain, consists of the telencephalon, or “end brain,” and the diencephalon, or “between brain.” The diencephalon forms the core of the forebrain, and the telencephalon forms the cerebral hemispheres.

Diencephalon. Three of the most forward brain segments form an enlarged dorsal horn and ventral horn with a narrow, deep, enlarged central canal—the third ventricle—separating the two sides. This region is called the diencephalon. The dorsal horn part of the diencephalon is the thalamus and subthalamus, and the ventral horn part is the hypothalamus (Fig. 17.17). The optic nerve (CN II) and retina are outgrowths of the diencephalon.

The thalamus consists of two large, egg-shaped masses, one on either side of the third ventricle. It is divided into several major parts, and each part is divided into distinct nuclei, which are the major relay stations for information going to and from the cerebral cortex. All sensory pathways have direct projections to thalamic nuclei, which convey the information...
to restricted areas of the sensory cortex. Coordination and integration of peripheral sensory stimuli occur in the thalamus, along with some crude interpretation of highly emotion-laden auditory experiences that not only occurs but also can be remembered. For example, a person can recover from a deep coma in which cerebral cortex activity is minimal and remember some of what was said at the bedside.

The thalamus also plays a role in relaying critical information regarding motor activities to and from selected areas of the motor cortex. Two neuronal circuits are significant in this regard. One is the pathway from the cerebral cortex to the pons and cerebellum and then, by way of the thalamus, back to the motor cortex. The second is the feedback circuit that travels from the cortex to the basal ganglia, then to the thalamus, and from the thalamus back to the cortex. The subthalamicus also contains movement control systems related to the basal ganglia.

Through its connections with the ascending reticular activating system, the thalamus processes neural influences that are basic to cortical excitatory rhythms (i.e., those recorded on the electroencephalogram), to essential sleep–wakeness cycles, and to the process of attending to stimuli. Besides their cortical connections, the thalamic nuclei have connections with each other and with neighboring nonthalamic brain structures such as the limbic system. Through their connections with the limbic system, some thalamic nuclei are involved in the relation between stimuli and the emotional responses they evoke.

Inferior to the thalamus and representing the ventral horn portion of the diencephalon is the hypothalamus. It also borders the third ventricle and includes a ventral extension, the hypothalamic nuclei have connections with each other and with neighboring nonthalamic brain structures such as the limbic system. Through their connections with the limbic system, some thalamic nuclei are involved in the relation between stimuli and the emotional responses they evoke.

The internal capsule is a broad band of projection fibers that lies between the thalamus medially and the basal ganglia laterally (see Fig. 17.17). It contains all of the fibers that connect the cerebral cortex with deeper structures, including the thalamus, basal ganglia, and parts of the thalamus provide associated movement function.

The cerebral cortex is the recently evolved six-layered neocortex, related reflexes and olfactory experience occur.

A thick area of myelinated axons called the corpus callosum connects the cerebral cortex of the two sides of the brain (see Fig. 17.17). Two smaller commissures, the anterior and posterior commissures, connect the two sides of the more specialized regions of the cerebrum and diencephalon.

The surfaces of the hemispheres are lateral (side), medial (area between the two sides of the brain), and basal (ventral). The cerebral cortex is the recently evolved six-layered neocortex. Many ridges and grooves are present on the surface of the hemispheres. A gyrus is the ridge between two grooves, and the groove is called a sulcus or fissure. The cerebral cortex is arbitrarily divided into lobes named after the bones that cover them: the frontal, parietal, temporal, and occipital lobes (see Fig. 17.16C).

**Basal Ganglia.** A section through the cerebral hemispheres reveals the surface of the cerebral cortex, a subcortical layer of white mass made up of masses of myelinated axons, and deep masses of gray matter—the basal ganglia that border the lateral ventricle (see Fig. 17.17). The basal ganglia lie on either side of the internal capsule, just lateral to the thalamus. The basal ganglia consist of the comma-shaped caudate (tailed) nucleus, the shield-shaped putamen, and the globus pallidus ("pale globe"). The term striatum ("striped body") refers to the caudate plus the putamen. Together, the globus pallidus and putamen make up the lentiform (lens-shaped) nucleus.

The basal ganglia supply axial and proximal unlearned and learned postures and movements, which enhance and add graceful quality to UMN-controlled manipulative movements. These background movement functions are called associated movements. Intact and functional basal ganglia provide arm swinging during walking and running. Basal ganglia also are involved in follow-through movements that accompany throwing a ball or swinging a club. As with the motor cortex, the nuclei on the left side control movement on the right side of the body, and vice versa. Circuits connecting the premotor cortex and supplementary motor cortex, the basal ganglia, and parts of the thalamus provide associated movements that accompany highly skilled behaviors. Parkinson disease, Huntington chorea, and some forms of cerebral palsy, among other dysfunctions involving the basal ganglia, result in a frequent or continuous release of abnormal postural or axial and proximal movement patterns. If damage to the basal ganglia is localized to one side, the movements occur on the opposite side of the body. These automatic movement patterns stop only in sleep, but in some conditions, the movements are so violent that falling asleep becomes difficult.

**Frontal Lobe.** The frontal lobe extends from the frontal pole to the central sulcus (i.e., fissure) and is separated from the temporal lobe by the lateral sulcus. Each frontal lobe can be subdivided rostrally into the frontal pole and laterally into the superior, middle, and inferior gyri, which continue on the undersurface over the eyes as the orbital cortex. These areas are associated with the medial thalamic nuclei, which also are related to the limbic system. Functionally, the prefrontal...
The precentral gyrus (area 4), next to the central sulcus, is the primary motor cortex (Fig. 17.18). This area of the cortex provides precise movement control for distal flexor muscles of the hands and feet and for the phonation apparatus required for speech. Just rostral to the precentral gyrus is a region of the frontal cortex called the premotor or motor association cortex. This region (area 8 and rostral area 6) is involved in the planning of complex learned movement patterns, and damage to these areas results in dyspraxia or apraxia. Such people can manipulate a screwdriver, for instance, but cannot use it to loosen a screw. The primary motor cortex and the association motor cortex are connected with lateral thalamic nuclei, through which they receive feedback information from the basal ganglia and cerebellum. On the medial surface of the hemisphere, the premotor area includes a supplementary motor cortex involved in the control of bilateral movement patterns requiring great dexterity.

**Parietal Lobe.** The parietal lobe of the cerebrum lies behind the central sulcus (i.e., postcentral gyrus) and above the lateral sulcus. A strip of cortex bordering the central sulcus is called the primary somatosensory cortex (areas 3, 1, and 2) because it receives very discrete sensory information from the lateral nuclei of the thalamus. Just behind the primary sensory cortex is the somesthetic association cortex (areas 5 and 7), which is connected with the thalamic nuclei and with the primary sensory cortex (see Fig. 17.18). This region is necessary for somesthetic perception (i.e., appreciation of the meaningfulness of integrated sensory information from various sensory systems), especially concerning perception of “where” the stimulus is in space and in relation to body parts. Localized lesions of this region can result in the inability to recognize the meaningfulness of an object (a condition called agnosia). With the person’s eyes closed, a screwdriver can be felt and described as to shape and texture. Nevertheless, the person cannot integrate the sensory information required to identify it as a screwdriver.

**Temporal Lobe.** The temporal lobe lies below the lateral sulcus and merges with the parietal and occipital lobes. It includes the temporal pole and three primary gyri, the superior, middle, and inferior gyri. The primary auditory cortex (area 41) involves the part of the superior temporal gyrus that extends into the lateral sulcus (see Fig. 17.18). This area is particularly important in discrimination of sounds entering opposite ears. It receives auditory input projections through the inferior colliculus of the midbrain and a ventrolateral thalamic nucleus. The more exposed part of the superior temporal gyrus involves the auditory association or perception area (area 22). The aspects of hearing that attach meaning to certain sound patterns require that this area function properly. The remaining portions of the temporal cortex are less well defined, but apparently are important in long-term memory recall. This is particularly true with respect to perception and memory of complex sensory patterns such as geometric figures and faces (i.e., recognition of “what” or “who” the stimulus is).

**Occipital Lobe.** The occipital lobe lies posterior to the temporal and parietal lobes and is arbitrarily separated from them (Fig. 17.18). The medial surface of the occipital lobe contains a deep sulcus extending from the limbic lobe to the occipital pole, the calcarine sulcus, which is surrounded by the primary visual cortex (area 17). Just superior and inferior and extending onto the lateral side of the occipital pole is the visual association cortex (areas 18 and 19). This area is closely connected with the primary visual cortex and with complex nuclei of the thalamus. Integrity of the association...
cortex is required for gnostic visual function, by which the meaningfulness of visual experience, including experiences of color, motion, depth perception, pattern, form, and location in space, takes place.

The neocortical areas of the parietal lobe, between the somesthetic and the visual cortices, have a function in relating the texture, or “feel,” and location of an object with its visual image. Between the auditory and visual association areas, the parietooccipital region is necessary for relating the meaningfulness of a sound and image to an object or person.

**Limbic System.** The medial aspect of the cerebrum is organized into concentric bands of cortex, the limbic system, which surrounds the connection between the lateral and third ventricles. The innermost band just above and below the cut surface of the corpus callosum is folded out of sight but is an ancient, three-layered cortex ending as the hippocampus in the temporal lobe. Just outside the folded area is a band of transitional cortex, which includes the cingulate and the parahippocampal gyri (Fig. 17.19). The limbic lobe has reciprocal connections with the medial and the intralaminar nuclei of the thalamus, with the deep nuclei of the cerebrum (e.g., amygdaloid nuclei, septal nuclei), and with the hypothalamus. Overall, this region of the brain is involved in emotional experience and in the control of emotion-related behavior. Stimulation of specific areas in this system can lead to feelings of dread, high anxiety, or exquisite pleasure. It also can result in violent behaviors, including attack, defense, or explosive and emotional speech.

**Meninges**

Inside the skull and vertebral column, the brain and spinal cord are loosely suspended and protected by several connective tissue sheaths called the meninges (Fig. 17.20). All surfaces of the spinal cord, brain, and segmental nerves are covered with a delicate connective tissue layer called the pia mater. Surface blood vessels and those that penetrate the brain and spinal cord are encased in this protective tissue layer. A second, very delicate, nonvascular, and waterproof layer, called the arachnoid, encloses the entire CNS. The CSF is contained in the subarachnoid space. Immediately outside the arachnoid is a continuous sheath of strong connective tissue, the dura mater, which provides the major protection for the brain and spinal cord. The cranial dura often splits into two layers, with the outer layer serving as the periosteum of the inner surface of the skull.

The inner layer of the dura forms two major infoldings—a longitudinal infolding called the falx cerebri and a transverse infolding called the tentorium cerebelli that anchor the brain to the skull (Fig. 17.21). The falx cerebri lies in the longitudinal fissure and separates the two cerebral hemispheres. It attaches to the crista of the ethmoid bone anteriorly and ends by becoming continuous with the tentorium cerebelli.
The tentorium cerebelli is a wide crescentic septum that acts as a hammock, supporting the occipital lobes above the cerebellum. The falx cerebri attaches to the tentorium cerebri and holds it up, giving it a tentlike appearance. The tentorium attaches to the petrous portion of the temporal bone and the dorsum sellae of the cranial floor, with a semicircular gap, or incisura, formed at the midline to permit the midbrain to pass forward from the posterior fossa. It also forms a tough septum, separating the anterior and middle cranial fossae, which contain the cerebral hemispheres, from the posterior fossa, found interiorly and containing the brain stem and cerebellum. This compartmentalization is the basis for the commonly used terms supratentorial (i.e., above the tentorium) and infratentorial (i.e., below the tentorium). The cerebral hemispheres and the diencephalon are supratentorial structures, and the pons, cerebellum, and medulla are infratentorial structures.

The tentorium and falx cerebri normally support and protect the brain, which floats in CSF within the enclosed space. During extreme trauma, however, the sharp edges of these folds can damage the brain. Space-occupying lesions such as enlarging tumors or hematomas can squeeze the brain against these edges or through the incisura of the tentorium (i.e., herniation). As a result, brain tissue can be compressed, contused, or destroyed, often causing permanent deficits.

**Ventricular System and Cerebrospinal Fluid**

The ventricular system is a series of CSF-filled cavities in the brain (Fig. 17.22). The CSF provides a supporting and protective fluid for the brain and spinal cord. CSF helps maintain a constant ionic environment that serves as a medium for diffusion of nutrients, electrolytes, and metabolic end products into the extracellular fluid surrounding CNS neurons and neuroglia. Filling the ventricles, the CSF supports the mass of the...
brain. Because it fills the subarachnoid space surrounding the CNS, a physical force delivered to either the skull or spine is to some extent diffused and cushioned.

A thin layer of neuralgial cells, collectively termed the ependyma, line the ventricles and central canal of the spinal cord. There is a tremendous expansion of the ependyma in the roof of the lateral, third, and fourth ventricles. The CSF is produced by tiny reddish masses of specialized ependymal cells and capillaries, called the choroid plexus, which project into the ventricles. CSF is an ultrafiltrate of blood plasma, composed mostly of water with other constituents, making it close to the composition of the brain extracellular fluid (Table 17.3). The amount of CSF produced daily is about 500 mL. The amount of CSF is approximately 125 to 150 mL in the ventricular system at any one time, meaning that the CSF is continuously being absorbed.

The CSF produced in the ventricles must flow through the interventricular foramen, the third ventricle, the cerebral aqueduct, and the fourth ventricle to exit from the ventricular system. Three openings, or foramina, allow the CSF to pass into the subarachnoid space. Two of these, the foramina of Luschka, are located at the lateral corners of the fourth ventricle. The third, the median foramen of Magendie, is in the midline at the caudal end of the fourth ventricle (see Fig. 17.23). CSF then passes down into the subarachnoid space that surrounds the spinal cord, mainly on its dorsal surface, and moves back up to the cranial cavity along its ventral surface.

Reabsorption of CSF into the vascular system occurs along the sides of the superior sagittal sinus in the anterior and middle fossae. The subarachnoid space has projections, the arachnoid villi, which penetrate the inner dura and walls of the superior sagittal sinus. Reabsorption of CSF into the vascular system occurs along a pressure gradient. The normal CSF pressure is in the range of 60 to 180 mm H2O in the lateral recumbent position. The microstructure of the arachnoid villi are such that if the CSF pressure falls below approximately 50 mm H2O, the passageways collapse, and reverse flow is blocked. Thus, the arachnoid villi function as one-way valves, permitting CSF outflow into the venous blood of the sagittal sinus but not allowing blood to pass into the arachnoid spaces.

**Blood-Brain and Cerebrospinal Fluid-Brain Barriers**

Maintenance of a chemically stable environment is essential to the function of the brain. In most regions of the body, extracellular fluid undergoes small fluctuations in pH and concentrations of hormones, amino acids, and potassium ions during routine daily activities such as eating and exercising. If the brain were to undergo such fluctuations, the result would be uncontrolled neural activity because some substances such as amino acids act as neurotransmitters, and ions such as potassium influence the threshold for neural firing. Two barriers, the blood–brain barrier and the CSF–brain barrier, provide the means for maintaining the stable chemical environment of the brain. Only water, carbon dioxide, and oxygen enter the brain with relative ease. The transport of other substances between the brain and the blood is slower and more controlled.

The blood–brain barrier depends on the unique characteristics of the brain capillaries. Endothelial cells of brain capillaries are joined by continuous tight junctions. In addition, most brain capillaries are surrounded by a basement membrane and by the processes of supporting cells of the brain, called astrocytes (Fig. 17.23). The blood–brain barrier permits passage of essential substances while excluding unwanted materials. Reverse transport systems remove materials from the brain. Large molecules, such as proteins and peptides, are largely excluded from crossing the blood–brain barrier. Acute cerebral lesions, such as trauma and infection, increase the permeability of the blood–brain barrier and alter brain concentrations of proteins, water, and electrolytes.

**FIGURE 17.23** – The three components of the blood–brain barrier: the astrocyte and astrocyte end feet that encircle the capillary, the capillary basement membrane, and the tight junctions that join the overlapping capillary endothelial cells.
The blood–brain barrier prevents many drugs from entering the brain. Most highly water-soluble compounds are excluded from the brain, especially molecules with high ionic charge such as many of the catecholamines. In contrast, many lipid-soluble molecules cross the lipid layers of the blood–brain barrier with ease. Some drugs, such as the antibiotic chloramphenicol, are highly lipid soluble and therefore enter the brain readily. Other medications have a low solubility in lipids and enter the brain slowly or not at all. Alcohol, nicotine, and heroin are very lipid soluble and rapidly enter the brain. Some substances that enter the capillary endothelium are converted by metabolic processes to a chemical form incapable of moving into the brain.

The cerebral capillaries are much more permeable at birth than in adulthood, and the blood–brain barrier develops during the early years of life. In severely jaundiced infants, bilirubin can cross the immature blood–brain barrier, producing kernicterus and brain damage. In adults, the mature blood–brain barrier prevents bilirubin from entering the brain, and the nervous system is not affected.

The ependymal cells covering the choroid plexus are linked together by tight junctions, forming a blood–CSF barrier to diffusion of many molecules from the blood plasma of choroid plexus capillaries to the CSF. Water is transported through the choroid epithelial cells by osmosis. Oxygen and carbon dioxide move into the CSF by diffusion, resulting in partial pressures roughly equal to those of plasma. The high sodium and low potassium contents of the CSF are actively regulated and kept relatively constant. Lipids and nonpeptide hormones diffuse through the barrier rather easily, but most large molecules, such as proteins, peptides, many antibiotics, and other medications, do not normally get through. The choroid epithelium uses energy in the form of adenosine triphosphate (ATP) to actively secrete many components into the CSF, including proteins, sodium ions, and several micronutrients such as vitamins C, B₆ (pyridoxine), and folate. Because the resultant CSF has a relatively high sodium content, the negatively charged chloride and bicarbonate diffuse into the CSF along an ionic gradient. The choroid cells also generate bicarbonate from carbon dioxide in the blood. This bicarbonate is important to the regulation of the pH of the CSF.

Mechanisms exist that facilitate the transport of other molecules such as glucose without energy expenditure. Ammonia, a toxic metabolite of neuronal activity, is converted to glutamine by astrocytes. Glutamine moves by facilitated diffusion through the choroid epithelium into the plasma. This exemplifies a major function of the CSF, that of providing a means of removal of toxic waste products from the CNS. Because the brain and spinal cord have no lymphatic channels, the CSF serves this function.

Several specific areas of the brain do not have a blood–CSF barrier. One such area is at the caudal end of the fourth ventricle (i.e., area postrema), where specialized receptors for the CSF carbon dioxide level influence respiratory function. Another area is the walls of the third ventricle, which permit hypothalamic neurons to monitor blood glucose levels.

This permits hypothalamic centers to sense and respond to changes in blood glucose levels through hunger and eating behaviors. Although most of the cells lining the third ventricle are ependymal cells, modified ependymal cells called tanyocytes are also present. Processes of tanyocytes extend through the glial lining of the third ventricle to terminate on blood vessels, neurons, or glial cells of the surrounding brain tissue.

### IN SUMMARY

In the adult, the spinal cord is in the upper two thirds of the spinal canal of the vertebral column. On transverse section, the spinal cord has an oval shape. Internally, the gray matter has the appearance of a butterfly or letter “H.” The dorsal horns contain the IA neurons and receive afferent information from dorsal root and other connecting neurons. The ventral horns contain the OA neurons and efferent LMNs that leave the cord by the ventral roots. Thirty-one pairs of spinal nerves (i.e., 8 cervical, 12 thoracic, 5 lumbar, 5 sacral, and 1 coccygeal) are present. Each pair communicates with its corresponding body segments. The spinal nerves and the blood vessels that supply the spinal cord enter the spinal canal through an intervertebral foramen. After entering the foramen, they divide into two branches, or roots, one of which enters the dorsolateral surface of the cord (i.e., dorsal root), carrying the axons of afferent neurons into the CNS. The other root leaves the ventrolateral surface of the cord (i.e., ventral root), carrying the axons of efferent neurons into the periphery. These two roots fuse at the intervertebral foramen, forming the mixed spinal nerve.

A reflex provides a highly reliable relation between a stimulus and a motor response. Its anatomic basis consists of an afferent (sensory) neuron, the connection with CNS neurons that communicate with the effector (motor) neuron, and the effector neuron that innervates a muscle or organ. Reflexes allow the sensory pathway for an involuntary motor response to a stimulus.

The brain can be divided into three parts—the hindbrain, midbrain, and forebrain. The hindbrain, consisting of the medulla oblongata, pons, and cerebellum, contains the neuronal circuits for the eating, breathing, and locomotive functions required for survival. CNs III and IV arise from the midbrain and CNs XII, XI, X, IX, VIII, VII, VI, and V are located in the hindbrain. The forebrain is the most rostral part of the brain. It consists of the diencephalon and the telencephalon. The dorsal horn part of the diencephalon comprises the thalamus and subthalamus, and the ventral horn part is the hypothalamus. The cerebral hemispheres are lateral outgrowths of the diencephalon.

The cerebral hemispheres are divided into lobes—the frontal, parietal, temporal, and occipital lobes—named after the bones of the skull that cover them. Contained in the frontal lobe are the prefrontal premotor area and primary motor cortex; the primary sensory cortex and somesthetic association area are in the parietal cortex; the
primary auditory cortex and the auditory association area are in the temporal lobe; and the primary visual cortex and association visual cortex are in the occipital lobe. The limbic system, which is involved in emotional experience and release of emotional behaviors, is located in the medial aspect of the cerebrum. These cortical areas are reciprocally connected with underlying thalamic nuclei through the internal capsule. Thalamic involvement is essential for normal forebrain function.

The brain is enclosed and protected by the dura mater, arachnoid, and pia mater. The protective CSF, in which the brain and spinal cord float, isolates them from minor and moderate trauma. CSF is secreted into the ventricles by the ependymal cells of the choroid plexus, circulates through the ventricular system, and is reabsorbed into the venous system through the arachnoid villi. The CSF–brain barrier and the blood–brain barrier protect the brain from substances in the blood that would disrupt brain function.

### THE AUTONOMIC NERVOUS SYSTEM

After completing this chapter, you should be able to meet the following objectives:

- Compare the sensory and motor components of the autonomic nervous system with those of the CNS.
- Compare the anatomic location and functions of the sympathetic and parasympathetic nervous systems.
- Describe neurotransmitter synthesis, release, and degradation, and receptor function in the sympathetic and parasympathetic nervous systems.

The ability to maintain homeostasis and perform the activities of daily living in an ever-changing physical environment is largely vested in the ANS. This portion of the nervous system functions at the subconscious level and is involved in regulating, adjusting, and coordinating vital visceral functions such as blood pressure and blood flow, body temperature, respiration, digestion, metabolism, and elimination. The ANS is strongly affected by emotional influences and is involved in many of the expressive aspects of behavior. Blushing, pallor, palpitations of the heart, clammy hands, and dry mouth are several emotional expressions mediated through the ANS. Biofeedback and relaxation exercises have been used for modifying the subconscious functions of the ANS.

As with the somatic nervous system, the ANS is represented in both the CNS and the PNS. The ANS has been defined as a general efferent system innervating visceral organs. The efferent outflow from the ANS has two divisions—the sympathetic nervous system and the parasympathetic nervous system. Afferent inputs to the ANS are provided by VA neurons and are not usually considered a part of the ANS. The two divisions of the ANS are usually viewed as having opposite and antagonistic actions. Exceptions are functions, such as sweating and regulation of arteriolar blood vessel diameter, which are controlled by a single division of the ANS, in this case the sympathetic nervous system.

The functions of the sympathetic nervous system include maintaining body temperature and adjusting blood vessels and blood pressure to meet the changing needs of the body. These adjustments occur in response to changes in routine activities of daily living, such as moving from the supine to the standing position. The sympathoadrenal system also can discharge as a unit when there is a critical threat to the integrity of the individual—the so-called fight-or-flight response. During a stress situation, the heart rate accelerates; blood pressure rises; blood flow shifts from the skin and gastrointestinal tract to the skeletal muscles and brain; blood sugar increases; the bronchioles and pupils dilate; the sphincters of the stomach and intestine and the internal sphincter of the urethra constrict; and the rate of secretion of exocrine glands involved in digestion diminishes. Emergency situations often require vasoconstriction and shunting of blood away from the skin and into the muscles and brain, a mechanism that, should a wound occur, provides for a reduction in blood flow and preservation of vital functions needed for survival. Sympathetic function is often summarized as “catabolic” in that its actions predominate during periods of pronounced energy expenditure, such as when survival is threatened.

In contrast to the sympathetic nervous system, the functions of the parasympathetic nervous system are concerned with conservation of energy, resource replenishment and storage, and maintenance of organ function during periods of minimal activity—the rest–digest response. The parasympathetic nervous system slows heart rate, stimulates gastrointestinal function and related glandular secretion, promotes bowel and bladder elimination, and contracts the pupil, protecting the retina from excessive light during periods when visual function is not vital to survival.

The sympathetic and parasympathetic nervous systems are continually active. The effect of this continual activity is referred to as tone. The tone of an effector organ or system can be increased or decreased and is usually regulated by a single division of the ANS (e.g., vascular smooth muscle tone is controlled by the sympathetic nervous system). Increased sympathetic activity produces local vasoconstriction from increased vascular smooth muscle tone, and decreased activity results in vasodilation due to decreased tone. In structures such as the sinoatrial node and atrophicentricular node of the heart, which are innervated by both divisions of the ANS, one division predominates in controlling tone. In this case, the tonically active parasympathetic nervous system exerts a constraining or braking effect on heart rate, and when parasympathetic outflow is withdrawn, similar to releasing a brake, the heart rate increases. The increase in heart rate that occurs with vagal withdrawal can be further augmented by sympathetic stimulation. Table 17.4 describes the responses of effector organs to sympathetic and parasympathetic impulses.

**KEY POINTS**

**THE AUTONOMIC NERVOUS SYSTEM**

- The ANS functions at the subconscious level and is responsible for maintaining homeostatic functions of the body.
- The ANS has two divisions—the sympathetic and parasympathetic systems. Although the two divisions function together, they are generally viewed as having opposite and antagonistic actions.
- The outflow of both divisions of the ANS consists of a two-neuron pathway: a preganglionic and a postganglionic neuron. Acetylcholine is the neurotransmitter for the preganglionic neurons for both ANS divisions, as well as the postganglionic neurons of the parasympathetic nervous system. Norepinephrine and epinephrine are the neurotransmitters for most sympathetic postganglionic neurons.

---

**Autonomic Efferent Pathways**

The outflow of both divisions of the ANS follows a two-neuron pathway. The first motor neuron, called the preganglionic neuron, lies in the intermediolateral cell column of the spinal cord or its equivalent location in the brain stem. The second motor neuron, called the postganglionic neuron, synapses with a preganglionic neuron in an autonomic ganglion in the PNS. The two divisions of the ANS differ as to location of their preganglionic cell bodies, the relative length of their preganglionic fibers, the nature of their peripheral responses, and their preganglionic and postganglionic neurotransmitters (see Table 17.4). This two-neuron pathway and the interneurons in the autonomic ganglia that add further modulation to ANS function are distinctly different from arrangements in the somatic nervous system.

Most visceral organs are innervated by both sympathetic and parasympathetic fibers (Fig. 17.24). Exceptions include structures such as blood vessels and sweat glands that have input from only one division of the ANS. The fibers of the sympathetic nervous system are distributed to effectors throughout the body, and, as a result, sympathetic actions tend to be more diffuse than those of the parasympathetic nervous system, in which there is a more localized distribution of fibers. The preganglionic fibers of the sympathetic nervous system may traverse a considerable distance and pass through several ganglia before synapsing with postganglionic neurons, and their terminals contact many postganglionic fibers. In some ganglia, the ratio of preganglionic to postganglionic cells may be 1:20; because of this, the effects of sympathetic stimulation are diffuse. Considerable overlap exists, and one ganglion cell may be supplied by several preganglionic fibers. In contrast to the sympathetic nervous system, the parasympathetic nervous system has its postganglionic neurons located very near or in the organ of innervation. Because the ratio of preganglionic to postganglionic communication is often 1:1, the effects of the parasympathetic nervous system are much more circumscribed.

**Sympathetic Nervous System**

The neurons of the sympathetic nervous system are located primarily in the intermediolateral cell column of the thoracic and upper lumbar segments (T1 to L2) of the spinal cord. Hence, the sympathetic nervous system is often called the thoracolumbar division of the ANS. These preganglionic neurons have axons that are largely myelinated and relatively short. Postganglionic neurons of the sympathetic nervous system are located in the paravertebral ganglia of the sympathetic chain of ganglia that lie on either side of the vertebral column or in
Figure 17.24 • The anatomy of the ANS.

Prevertebral sympathetic ganglia such as the celiac ganglia. Besides postganglionic efferent neurons, the sympathetic ganglia contain neurons of the internuncial, short-axon type, similar to those associated with complex circuitry in the brain and spinal cord. Many of these inhibit and others modulate preganglionic to postganglionic transmission.

The axons of the preganglionic neurons leave the spinal cord through the ventral roots of the spinal nerves (T1 to L2), enter the ventral primary rami, and leave the spinal nerve through white rami of the rami communicantes to reach the paravertebral ganglionic chain (Fig. 17.25). In the sympathetic chain of ganglia, preganglionic fibers may synapse with neurons of the ganglion they enter, pass up or down the chain and synapse with one or more ganglia, or pass through the chain and move outward through a splanchnic nerve to terminate in prevertebral ganglia (i.e., celiac, superior mesenteric, or inferior mesenteric) scattered along the dorsal aorta and its branches.

Preganglionic fibers from the thoracic segments of the cord pass upward to form the cervical chain connecting the inferior, middle, and superior cervical sympathetic ganglia with the rest of the sympathetic chain at lower levels. Preganglionic sympathetic axons of the cervical and lower lumbosacral chain ganglia spread further through nerve plexuses along continuations of the great arteries. Cranial structures, particularly blood vessels, are innervated by the spread of postganglionic axons along the external and internal carotid arteries into the face and the cranial cavity. The sympathetic fibers from T1 usually continue up the sympathetic chain into the head; those from T2 pass into the neck; those from T3, T4, T5, and T6 travel to the heart; those from T3, T4, T5, and T6 proceed to the thoracic viscera; those from T7, T8, T9, T10, and T11 pass to the abdominal
viscera; and those from T12, L1, L2, and L3 pass to the kidneys and pelvic organs. Many preganglionic fibers from the fifth to the last thoracolumbar segments pass through the paravertebral ganglia to continue as the splanchnic nerves. Most of these fibers do not synapse until they reach the celiac or superior mesenteric ganglion; others pass to the adrenal medulla.

The adrenal medulla, which is part of the sympathetic nervous system, contains postganglionic sympathetic neurons that secrete sympathetic neurotransmitters directly into the bloodstream. Some postganglionic fibers, all of which are unmyelinated, exit the paravertebral ganglia to enter the spinal nerve branches. These fibers innervate the sweat glands, piloerector muscles of the hair follicles, all blood vessels of the skin and skeletal muscles, and the CNS itself.

**Parasympathetic Nervous System**

The preganglionic fibers of the parasympathetic nervous system, also called the craniosacral division of the ANS, originate in some segments of the brain stem and sacral segments of the spinal cord. The central regions of origin are the midbrain, pons, medulla oblongata, and the sacral spinal cord. The midbrain outflow passes through the oculomotor nerve (CN III) to the ciliary ganglion that lies in the orbit behind the eye; it supplies the pupil and the ciliary muscles that control lens thickness for accommodation. From the caudal pontine outflow originates the preganglionic fibers of the intermedius component of the facial nerve (CN VII) complex. This outflow synapses in the submandibular ganglion, which sends postganglionic fibers to supply the submandibular and sublingual glands. In addition, preganglionic fibers are distributed to the pterygopalatine ganglia to synapse on postganglionic neurons that supply the lacrimal and nasal glands. Fibers in the glossopharyngeal nerve (CN IX) synapse in the otic ganglia, which supply the parotid salivary glands. Approximately 75% of parasympathetic efferent fibers are carried in the vagus nerve (CN X). The vagus nerve provides parasympathetic innervation for the heart, trachea, lungs, esophagus, stomach, small intestine, proximal half of the colon, liver, gallbladder, pancreas, kidneys, and upper portions of the ureters. The gastrointestinal tract has its own intrinsic network of ganglionic cells located between the smooth muscle layers, called the enteric nervous system,
which controls local peristaltic and secretory functions. The action of the enteric nervous system can be modified by the activity of the ANS.

Sacral preganglionic axons leave the S2 to S4 segmental nerves by gathering into the pelvic nerves, also called the *nervi erigentes*. The pelvic nerves leave the sacral plexus on each side of the cord and distribute their peripheral fibers to the bladder, uterus, urethra, prostate, distal portion of the transverse colon, descending colon, and rectum. Sacral parasympathetic fibers also supply the venous outflow from the external genitalia to facilitate erectile function.

Except for CNs III, VII, and IX, which synapse in discrete ganglia, the long parasympathetic preganglionic fibers pass uninterrupted to short postganglionic fibers in the organ walls. In the walls of these organs, postganglionic neurons send axons to smooth muscle and glandular cells that modulate their functions.

### Central Integrative Pathways

General VA fibers accompany the sympathetic and parasympathetic outflow into the spinal and CNs, bringing chemoreceptor pressure, organ capsule stretch, and nociceptive information from organs of the viscera to the brain stem, thoracolumbar cord, and sacral cord. Local reflex circuits relating VA and autonomic efferent activity are integrated into a hierarchic control system in the spinal cord and brain stem. Progressively greater complexity in the responses and greater precision in their control occur at each higher level of the nervous system. Most visceral reflexes contain contributions from the LMNs that innervate skeletal muscles as part of their response patterns. The distinction between purely visceral and somatic reflex hierarchies becomes less and less meaningful at the higher levels of hierarchic control and behavioral integration.

The hypothalamus serves as the major control center for most of the autonomically mediated functions. The hypothalamus, with connections to the cerebral cortex, the limbic system, and the pituitary gland, is in a prime position to receive, integrate, and transmit information to other areas of the nervous system. Signals from the hypothalamus can affect almost all the brain stem control centers. For example, stimulation of certain areas, mainly in the posterior hypothalamus, can cause the cardiovascular control centers to increase the arterial blood pressure to more than twice normal. Likewise, other hypothalamic centers control body temperature and increase salivation and gastrointestinal activity.

Reflex adjustments of cardiovascular and respiratory function occur at the level of the brain stem. A prominent example is the carotid sinus baroreflex. Increased blood pressure in the carotid sinus results in increased discharge from afferent fibers that travel by way of CN IX to cardiovascular centers in the brain stem. These centers increase the activity of descending efferent vagal fibers that slow heart rate, while inhibiting sympathetic fibers that increase heart rate and blood vessel tone. Striking features of the ANS are the rapidity and intensity with which it can change visceral function. Within 3 to 5 seconds, it can increase the heart rate to approximately twice its resting level. Bronchial smooth muscle tone is largely controlled by parasympathetic fibers carried in the vagus nerve. These nerves produce mild to moderate constriction of the bronchioles.

Other important ANS reflexes are located at the level of the spinal cord. As with other spinal reflexes, these reflexes are modulated by input from higher centers. When there is a loss of communication between the higher centers and the spinal reflexes, as occurs in spinal cord injury, these reflexes function in an unregulated manner. This results in uncontrolled sweating, vasomotor instability, and reflex bowel and bladder function.

### Autonomic Neurotransmission

The generation and transmission of impulses in the ANS occur in the same manner as in other neurons. There are self-propagating action potentials with transmission of impulses across synapses and other tissue junctions by neurohumoral transmitters. However, the somatic motor neurons that innervate skeletal muscles divide into many branches, with each branch innervating a single muscle fiber; in contrast, the distribution of postganglionic fibers of the ANS forms a diffuse neural plexus at the site of innervation. The membranes of the cells of many smooth muscle fibers are connected by conductive protoplasmic bridges, called *gap junctions*, that permit rapid conduction of impulses through whole sheets of smooth muscle, often in repeating waves of contraction. Autonomic neurotransmitters released near a limited portion of these fibers provide a modulating function extending to many effectors. Smooth muscle layers of the gut and of the bladder wall are examples. Sometimes, isolated smooth muscle cells are individually innervated by the ANS, such as the piloerector cells that elevate the hair on the skin during cold exposure.

The main neurotransmitters of the ANS are acetylcholine and the catecholamines, epinephrine and norepinephrine (Fig. 17.26). Acetylcholine is released at all preganglionic synapses in the autonomic ganglia of both sympathetic and parasympathetic nerve fibers and from postganglionic synapses of all parasympathetic nerve endings. It is also released at sympathetic nerve endings that innervate the sweat glands and cholinergic vasodilator fibers found in skeletal muscle. Norepinephrine is released at most sympathetic nerve endings. The adrenal medulla, which is a modified prevertebral sympathetic ganglion, produces epinephrine along with small amounts of norepinephrine. Dopamine, which is an intermediate compound in the synthesis of norepinephrine, also acts as a neurotransmitter. It is the principal inhibitory transmitter of internuncial neurons in the sympathetic ganglia. It also has vasodilator effects on renal, splanchnic, and coronary blood vessels when given intravenously and is sometimes used in the treatment of shock.

### Acetylcholine and Cholinergic Receptors

Acetylcholine is synthesized in the cholinergic neurons from choline and acetyl coenzyme A (acetyl CoA; Fig. 17.27A).
After acetylcholine is secreted by the cholinergic nerve endings, it is rapidly broken down by the enzyme acetylcholinesterase. The choline molecule is transported back into the nerve ending, where it is used again in the synthesis of acetylcholine.

Receptors that respond to acetylcholine are called cholinergic receptors. Two types of cholinergic receptors are known—muscarinic and nicotinic. Muscarinic receptors are present on the innervational targets of postganglionic fibers of the parasympathetic nervous system and the sweat glands, which are innervated by the sympathetic nervous system. Nicotinic receptors are found in autonomic ganglia and the end plates of skeletal muscle. Acetylcholine is excitatory to most muscarinic and nicotinic receptors, except those in the heart and lower esophagus, where it has an inhibitory effect. The drug atropine is an antimuscarinic or muscarinic cholinergic blocking drug that prevents the action of acetylcholine at excitatory and inhibitory muscarinic receptor sites. Because it is a muscarinic blocking drug, it exerts little effect at nicotinic receptor sites.

**Catecholamines and Adrenergic Receptors**

The catecholamines, which include norepinephrine, epinephrine, and dopamine, are synthesized in the axoplasm of sympathetic nerve terminal endings from the amino acid tyrosine (see Fig. 17.27B). During catecholamine synthesis, tyrosine is hydroxylated (i.e., has a hydroxyl group added) to form DOPA, and DOPA is decarboxylated (i.e., has a carboxyl group removed) to form dopamine. Dopamine in turn is hydroxylated to form norepinephrine. In the adrenal gland, an additional step occurs during which norepinephrine is methylated (i.e., a methyl group is added) to form epinephrine.

Each step in sympathetic neurotransmitter synthesis requires a different enzyme, and the type of neurotransmitter produced depends on the types of enzymes that are available in a nerve terminal. For example, the postganglionic sympathetic neurons that supply blood vessels synthesize norepinephrine, but postganglionic neurons in the adrenal medulla produce epinephrine or norepinephrine. Epinephrine accounts for approximately 80% of the catecholamines released from the adrenal gland. The synthesis of epinephrine by the adrenal medulla is influenced by glucocorticoid secretion from the adrenal cortex. These hormones are transported through an intra-adrenal vascular network from the adrenal cortex to the adrenal medulla, where they cause the sympathetic neurons to increase their production of epinephrine through increased enzyme activity. Thus, any situation sufficiently stressful to evoke increased levels of glucocorticoids also increases epinephrine levels. As the catecholamines are synthesized, they are stored in vesicles. The final step of norepinephrine synthesis occurs in these vesicles. When an action potential reaches an axon terminal, the neurotransmitter molecules are released from the storage vesicles. The storage vesicles provide a means for concentrated storage of the catecholamines and protect the neurotransmitters from the cytoplasmic enzymes that degrade them.

Besides neuronal synthesis, a second major mechanism exists for the replenishment of norepinephrine in sympathetic nerve terminals. This mechanism consists of the active recapture or reuptake of the released neurotransmitter into the nerve terminal. Between 50% and 80% of the norepinephrine released during an action potential is removed from the synaptic area by an active reuptake process. This process stops the action of the neurotransmitter and allows it to be reused by the neuron. The remainder of the released catecholamines diffuses into the surrounding tissue fluids or is degraded by
In vascular smooth muscle, excitation of α receptors causes vasoconstriction, and excitation of β receptors causes vasodilation. Endogenously and exogenously administered norepinephrine produces marked vasoconstriction of the blood vessels in the skin, kidneys, and splanchnic circulation that are supplied with α receptors. The β receptors are most prevalent in the heart, the blood vessels of skeletal muscle, and the bronchioles. Blood vessels in skeletal muscle have α and β receptors. In these vessels, high levels of norepinephrine produce vasoconstriction; low levels produce vasodilation. The low levels are thought to have a diluting effect on norepinephrine levels in the arteries of these blood vessels so that the β effect predominates. With respect to vessels having few receptors, such as those that supply the brain, norepinephrine has little effect.

α-Adrenergic receptors have been further subdivided into α₁ and α₂ receptors and β-adrenergic receptors into β₁ and β₂ receptors. β₁-Adrenergic receptors are found primarily in...
the heart and can be selectively blocked by β, receptor blocking drugs. β,-Adrenergic receptors are found in the bronchioles and in other sites that have β-mediated functions. α,-Adrenergic receptors are found primarily in postsynaptic effector sites; they mediate responses in vascular smooth muscle. α,-Adrenergic receptors are mainly located presynaptically and can inhibit the release of norepinephrine from sympathetic nerve terminals. α,-Adrenergic receptors are abundant in the CNS and are thought to influence the central control of blood pressure.

The various classes of adrenergic receptors provide a mechanism by which the same adrenergic neurotransmitter can have many selective effects on different effector cells. This mechanism also permits neurotransmitters carried in the bloodstream, whether from neuroendocrine secretion by the adrenal gland or from subcutaneously or intravenously administered drugs, to produce the same effects. The catecholamines produced and released from sympathetic nerve endings are called endogenous neuromediators. Sympathetic nerve endings also can be activated by exogenous forms of these neuromediators, which reach the nerve endings through the bloodstream after being injected into the body or administered orally. These drugs mimic the action of the neuromediators and are said to have a sympathomimetic action. Other drugs can selectively block the receptor sites on the neurons and temporarily prevent the neurotransmitter from exerting its action.

**IN SUMMARY**

The ANS regulates, adjusts, and coordinates the visceral functions of the body. The ANS, which is divided into the sympathetic and parasympathetic systems, is an efferent system. It receives its afferent input from VA neurons. The ANS has CNS and PNS components. The outflow of the sympathetic and parasympathetic nervous systems follows a two-neuron pathway, which consists of a preganglionic neuron in the CNS and a postganglionic neuron located outside the CNS. Sympathetic fibers leave the CNS at the thoracolumbar level, and the parasympathetic fibers leave at the cranial and sacral levels. The sympathetic and parasympathetic nervous systems can have opposing effects on visceral function—if one excites, the other inhibits. The hypothalamus serves as the major control center for most ANS functions; local reflex circuits relaying VA and autonomic efferent activity are integrated in a hierarchic control system in the spinal cord and brain stem.

The main neurotransmitters for the ANS are acetylcholine and the catecholamines, epinephrine and norepinephrine. Acetylcholine is the transmitter for all preganglionic neurons, for postganglionic parasympathetic neurons, and for selected postganglionic sympathetic neurons. The catecholamines are the neurotransmitters for most postganglionic sympathetic neurons. Neurotransmitters exert their target action through specialized cell surface receptors—cholinergic receptors that bind acetylcholine and adrenergic receptors that bind the catecholamines. The cholinergic receptors are divided into nicotinic and muscarinic receptors, and adrenergic receptors are divided into α and β receptors. Different receptors for the same transmitter at various sites in the same tissue or in other tissues result in differences in tissue responses to the same transmitter. This arrangement also permits the use of pharmacologic agents that act at specific receptor types.

**REVIEW EXERCISES**

1. Herpes zoster or shingles is a painful vesicular skin eruption involving the dermatomal distribution of a general SA nerve that is caused by reactivation of the chickenpox virus (varicella–zoster virus) that has remained dormant in the dorsal root ganglion since a childhood infection.
   A. **Explain the reactivation of the varicella–zoster virus.**

2. An event such as cardiac arrest, which produces global ischemia of the brain, can produce a selective loss of recent memory and cognitive skills, while the more vegetative and life-sustaining functions such as breathing are preserved.
   A. **Use principles related to the development of the nervous system and hierarchy of control to explain why.**

3. Usually spinal cord injury or disease produces both sensory and motor deficits. An exception is infection by the poliomyelitis virus, which produces weakness and paralysis without loss of sensation in the affected extremities.
   A. **Explain, using information on the cell column organization of the spinal cord.**

4. The functions of the sympathetic nervous system are often described in relation to the “fight-or-flight” response. Using this description, explain the physiologic advantage for the following distribution of sympathetic nervous system receptors:
   A. **The presence of β, receptors on the blood vessels that provide blood flow to the skeletal muscles during “fight or flight,” and the presence of α, receptors on the resistance vessels that control blood pressure.**
   B. **The presence of acetylcholine receptors on the sweat glands that allow for evaporative loss of body heat during “fight or flight,” and the presence of α, receptors that constrict the skin vessels that control blood flow to the skin.**
   C. **The presence of β, receptors that produce relaxation in the detrusor muscle of the bladder during “fight or flight,” and the presence of α, receptors that produce contraction of the smooth muscle in the internal sphincter of the bladder.”**

The somatosensory component of the nervous system provides an awareness of body sensations such as touch, temperature, body position, and pain. Other sensory components of the nervous system include the special senses of vision, hearing, smell, and taste. These special senses are discussed in other chapters. The sensory receptors for somatosensory function consist of discrete nerve endings in the skin and other body tissues. Between 2 and 3 million sensory neurons deliver a steady stream of encoded information. Only a small proportion of this information reaches awareness. Instead, most of the information provides input essential for a myriad of reflex and automatic mechanisms that keep us alive and manage our functioning.

This chapter is organized into two distinct parts. The first part describes the organization and control of somatosensory function, and the second focuses on pain as a somatosensory modality.
The somatosensory system is designed to provide the central nervous system (CNS) with information on touch, temperature, body position, and pain related to deep and superficial body structures. Sensory neurons can be divided into three types that vary in distribution and the type of sensation detected: general somatic, special somatic, and general visceral. General somatic afferent neurons have branches with widespread distribution throughout the body and with many distinct types of receptors that result in sensations such as pain, touch, and temperature. Special somatic afferent neurons have receptors located primarily in muscles, tendons, and joints. These receptors sense position and movement of the body. General visceral afferent neurons have receptors on various visceral structures that sense fullness and discomfort.

**Sensory Systems**

Sensory systems can be conceptualized as a serial succession of neurons consisting of first-order, second-order, and third-order neurons. First-order neurons transmit sensory information from the periphery to the CNS. Second-order neurons communicate with various reflex networks and sensory pathways in the spinal cord and travel directly to the thalamus. Third-order neurons relay information from the thalamus to the cerebral cortex (Fig. 18.1).

These three primary levels of neural integration provide the organizing framework of the somatosensory system:
- The sensory units, which contain the sensory receptors
- The ascending pathways
- The central processing centers in the thalamus and cerebral cortex

Sensory information usually is relayed and processed in a cephalad (toward the head) direction by the three orders of neurons. Many interneurons process and modify the sensory information at the level of the second- and third-order neurons, and many more participate before coordinated and appropriate learned movement responses occur. The number of participating neurons increases exponentially from the primary through the secondary and the secondary through the tertiary levels.

**KEY POINTS**

**THE SOMATOSENSORY SYSTEM**
- The somatosensory system relays information about four major modalities: touch, temperature, body position, and pain.
- Somatosensory information is sequentially transmitted over three types of neurons: first-order neurons, which transmit information from sensory receptors to dorsal horn neurons; second-order CNS association neurons, which communicate with various reflex circuits and transmit information to the thalamus; and third-order neurons, which forward the information from the thalamus to the sensory cortex.

**The Sensory Unit**

The somatosensory experience arises from information provided by a variety of receptors distributed throughout the body. These receptors monitor four major types or modalities of sensation—stimulus discrimination, tactile sensation, thermal sensation, and position sensation.

Each of the somatosensory modalities is mediated by a distinct system of receptors and pathways to the brain. However, all somatosensory information from the limbs and trunk shares a common class of sensory neurons called dorsal root ganglion neurons. Somatosensory information from the face and cranial structures is transmitted by...
the trigeminal sensory neurons, which function in the same manner as the dorsal root ganglion neurons. The cell body of the dorsal root ganglion neuron, its peripheral branch (which innervates a small area of periphery), and its central axon (which projects to the CNS) form what is called a sensory unit.

The fibers of different dorsal root ganglion neurons conduct impulses at varying rates, ranging from 0.5 to 120 m/second. This rate depends on the diameter of the nerve fiber. There are three types of nerve fibers that transmit somatosensory information—types A, B, and C. Type A fibers, which are myelinated, have the fastest rate of conduction and convey cutaneous pressure and touch sensation, cold sensation, mechanical pain, and heat pain. Type B fibers, which also are myelinated, transmit information from cutaneous and subcutaneous mechanoreceptors. The unmyelinated type C fibers have the smallest diameter and the slowest rate of conduction. They convey warm–hot sensation and mechanical and chemical as well as heat- and cold-induced pain sensation. One of the biggest problems for managing pain is to identify the etiology of the pain. Identifying the etiology of pain is especially difficult in areas such as the lower urinary tract. The lower urinary tract has both myelinated (Aδ) and unmyelinated C fibers, which provide afferent innervations to this area. Evidence suggests that by using a Neurometer in this area, a more comprehensive diagnosis of sensory function can be made. In turn, more effective pharmacological and non-pharmacological interventions could be recommended.

**Dermatomal Pattern of Dorsal Root Innervation**

The somatosensory innervation of the body, including the head, retains a basic segmental organizational pattern that was established during embryonic development. Thirty-three paired spinal nerves provide sensory and motor innervation of the body wall, the limbs, and the viscera. Sensory input to each spinal cord segment is provided by sensory neurons with cell bodies in the dorsal root ganglia.

The region of the body wall that is supplied by a single pair of dorsal root ganglia is called a dermatome. These dorsal root ganglion–innervated strips occur in a regular sequence moving upward from the second coccygeal segment through the cervical segments, reflecting the basic segmental organization of the body and the nervous system (Fig. 18.2). The cranial nerves that innervate the head send their axons to equivalent nuclei in the brain stem. Neighboring dermatomes overlap one another sufficiently so that a loss of one dorsal root or root ganglion results in reduced but not total loss of sensory innervation of a dermatome (Fig. 18.3). Using dermatome maps...
FIGURE 18.3 • The dermatomes formed by the peripheral processes of adjacent spinal nerves overlap on the body surface. The central processes of these fibers also overlap in their spinal distribution.

can help in interpreting the level and extent of sensory deficits that are the result of segmental nerve and spinal cord damage. The information obtained from this exercise can assist in determining the most effective pain management plan.

**Spinal Circuitry and Ascending Neural Pathways**

On entry into the spinal cord, the central axons of the somatosensory neurons branch extensively and project to neurons in the spinal cord gray matter. Some branches become involved in local spinal cord reflexes and directly initiate motor reflexes (e.g., flexor-withdrawal reflex). Two parallel pathways, the **discriminative pathway** and the **anterolateral pathway**, carry the information from the spinal cord to the thalamic level of the brain, where basic sensation begins. The discriminative pathway crosses at the base of the medulla, and the anterolateral pathway crosses within the first few segments of entering the spinal cord. These pathways relay information to the brain for three purposes—perception, arousal, and motor control. The advantages of having a two-pathway system include the following:

- Sensory information can be handled in two different ways.
- If one pathway is damaged, the other still can provide input.

**The Discriminative Pathway.** The discriminative pathway, also known as the dorsal column–medial lemniscal pathway, is used for the rapid transmission of sensory information such as discriminative touch. It contains branches of primary afferent axons that travel up the ipsilateral (i.e., same side) dorsal columns of the spinal cord white matter and synapse with highly evolved somatosensory input association neurons in the medulla. The discriminative pathway uses only three neurons to transmit information from a sensory receptor to the somatosensory strip of parietal cerebral cortex of the opposite side of the brain:

1. The primary dorsal root ganglion neuron, which projects its central axon to the dorsal column nuclei
2. The dorsal column neuron, which sends its axon through a rapid conducting tract, called the **medial lemniscus**. It then crosses at the base of the medulla and travels to the thalamus on the opposite side of the brain, where basic sensation begins.
3. The thalamic neuron, which projects its axons through the somatosensory radiation to the primary sensory cortex (Fig. 18.4A)

The medial lemniscus is joined by fibers from the sensory nucleus of the trigeminal nerve (cranial nerve V) that supplies the face. Sensory information arriving at the sensory cortex by this route can be discretely localized and discriminated in terms of intensity.

A distinct feature of the discriminative pathway is that it relays precise information regarding spatial orientation. This is the only pathway taken by the sensations of muscle and joint movement, vibration, and delicate discriminative touch, as is required to differentiate correctly the location of touch on the skin at two neighboring points (i.e., two-point discrimination). An important function of the discriminative pathway is to integrate the input from multiple receptors. The sense of shape and size of an object in the absence of visualization, called **stereognosis**, is based on precise afferent information from muscle, tendon, and joint receptors. For example, a screwdriver is perceived as being different from a knife in terms of its texture (tactile sensibility) and shape based on the relative position of the fingers as they move over the object. This complex interpretive perception requires that both the discriminative system and the higher-order parietal association cortex are functioning properly. If the discriminative somatosensory pathway is functional but the parietal association cortex has become discretely damaged, the person can correctly describe the object but does not recognize that it is a screwdriver. This deficit is called **astereognosis**.

**The Anterolateral Pathway.** The anterolateral pathways (anterior and lateral spinothalamic pathways) consist of bilateral, multisynaptic, slow-conducting tracts. These pathways provide transmission of sensory information such as pain, thermal sensations, crude touch, and pressure that does not require discrete localization of signal source or fine discrimination of intensity. The fibers of the anterolateral pathway originate in the dorsal horns of the spinal cord, where the dorsal root neurons enter the spinal cord. They cross in the anterior commissure, within a few segments of origin, to the opposite anterolateral pathway, where they ascend upward toward the brain. The spinothalamic tract fibers synapse with several nuclei in the thalamus, but en route they give off numerous branches that travel to the reticular activating system of the brain stem. These projections provide the basis for increased wakefulness or awareness after strong somatosensory stimulation and for the generalized startle reaction that occurs with sudden and intense stimuli. They also stimulate autonomic nervous system responses, such as a rise in heart rate and blood pressure, dilation of the pupils,
and the pale, moist skin that results from constriction of the cutaneous blood vessels and activation of the sweat glands.

There are two subdivisions in the anterolateral pathway—the neospinothalamic tract and the paleospinothalamic tract (Fig. 18.4B). The neospinothalamic tract consists of a sequence of at least three neurons with long axons. It provides for relatively rapid transmission of sensory information to the thalamus. The paleospinothalamic tract, which is phylogenetically older than the neospinothalamic system, consists of bilateral, multisynaptic, slow-conducting tracts that transmit sensory signals that do not require discrete localization or discrimination of fine gradations in intensity. This slower-conducting pathway also projects into the intralaminar nuclei of the thalamus, which have close connections with the limbic cortical systems. The circuitry gives touch its affective or emotional aspects, such as the particular unpleasantness of heavy pressure and the peculiar pleasantness of the tickling and gentle rubbing of the skin.

Central Processing of Somatosensory Information

Perception, or the final processing of somatosensory information, involves awareness of the stimuli, localization and discrimination of their characteristics, and interpretation of their meaning. As sensory information reaches the thalamus, it begins to enter the level of consciousness. In the thalamus, the sensory information is roughly localized and perceived as a crude sense. The full localization, discrimination of the intensity, and interpretation of the meaning of the stimuli require processing by the somatosensory cortex.

The somatosensory cortex is located in the parietal lobe, which lies behind the central sulcus and above the lateral sulcus (Fig. 18.5). The strip of parietal cortex that borders the central sulcus is called the primary somatosensory cortex because it receives primary sensory information by direct projections from the thalamus. The somatosensory association cortex reflects the density of cortical neurons devoted to sensory input from afferents in corresponding peripheral areas. Most of the cortical surface is devoted to areas of the body such as the thumb, forefinger, lips, and tongue, where fine touch and pressure discrimination are essential for normal function.

Parallel to and just behind the primary somatosensory cortex (i.e., toward the occipital cortex) lie the somatosensory association areas, which are required to transform the raw material of sensation into meaningful learned perception. Most of the perceptive aspects of body sensation, or somesthesia, require the function of this parietal association cortex.
The perceptive aspect, or meaningfulness, of a stimulus pattern involves the integration of present sensation with past learning. For instance, a person’s past learning plus present tactile sensation provides the perception of sitting on a soft chair rather than on a hard bicycle seat.

**Sensory Modalities**

Somatosensory experience can be divided into modalities, a term used for qualitative, subjective distinctions between sensations such as touch, heat, and pain. These experiences require the function of sensory receptors and forebrain structures in the thalamus and cerebral cortex. Sensory experience also involves quantitative sensory discrimination or the ability to distinguish between different levels of sensory stimulation.

The receptive endings of different afferent neurons are particularly sensitive to specific forms of physical and chemical energy. They can initiate action potentials to many forms of energy at high energy levels, but they usually are highly tuned to be differentially sensitive to low levels of a particular energy type. For example, a receptive ending may be particularly sensitive to a small increase in local skin temperature. Stimulating the ending with electric current or strong pressure also can result in action potentials. The amount of energy required, however, is much greater than it is for a change in temperature. Other afferent sensory terminals are most sensitive to slight indentations of the skin, and their signals are subjectively interpreted as touch. Cool versus warm, sharp versus dull pain, and delicate touch versus deep pressure are all based on different populations of afferent neurons or on central integration of simultaneous input from several differently tuned afferents.

When information from different primary afferents reaches the forebrain, where subjective experience occurs, the qualitative differences between warmth and touch are called sensory modalities. Although the receptor-detected information is relayed to the thalamus and cortex over separate pathways, the experience of a modality, such as cold versus warm, is uniquely subjective.

**Stimulus Discrimination**

The ability to discriminate the location of a somesthetic stimulus is called acuity and is based on the sensory field in a dermatome innervated by an afferent neuron. High acuity (i.e., the ability to make fine discriminations of location) requires a high density of innervation by afferent neurons. For example, acuity is highest on the lips and cheek but lower on the arm or back. High acuity also requires a projection system through the CNS to the forebrain that preserves distinctions between levels of activity in neighboring sensory fields. Receptors or receptive endings of primary afferent neurons differ as to the intensity at which they begin to fire. For instance, it is possible to assess two-point discrimination by using an open paper clip with its ends bent together to 5 mm apart. When placed on the lips or cheek, the person will readily detect two points of contact. On the back or arm, the ends of the paper clip must be moved progressively farther apart before two points of contact can be detected.

**Tactile Sensation**

The tactile system, which relays sensory information regarding touch, pressure, and vibration, is considered the basic somatosensory system. Loss of temperature or pain sensitivity leaves the person with no awareness of deficiency. If the tactile system is lost, however, total anesthesia (i.e., numbness) of the involved body part results.

Touch sensation results from stimulation of tactile receptors in the skin and in tissues immediately beneath the skin, pressure from deformation of deeper tissues, and vibration from rapidly repetitive sensory signals. There are at least six types of specialized tactile receptors in the skin and deeper structures—free nerve endings, Meissner corpuscles, Merkel disks, pacinian corpuscles, hair follicle end organs, and Ruffini end organs (Fig. 18.6).

Free nerve endings are found in skin and many other tissues, including the cornea. They detect touch and pressure. Meissner corpuscles are elongated, encapsulated nerve endings present in nonhairy parts of the skin. They are particularly abundant in the fingertips, lips, and other areas where the sense of touch is highly developed. Merkel disks are dome-shaped receptors found in nonhairy areas and in hairy parts of the skin. In contrast to Meissner corpuscles, which adapt within a fraction of a second, Merkel disks transmit an initial strong signal that diminishes in strength but is slow in adapting. For this reason, Meissner corpuscles are particularly sensitive to the movement of very light objects over the surface of the skin and to low-frequency vibration. Merkel disks are responsible for giving steady-state signals that allow for continuous determination of touch against the skin.

The pacinian corpuscle is located immediately beneath the skin and deep in the fascial tissues of the body. This type
of receptor, which is stimulated by rapid movements of the tissues and adapts within a few hundredths of a second, is important in detecting direct pressure changes and tissue vibration.\(^2\) The hair follicle end organ consists of afferent unmyelinated fibers entwined around most of the length of the hair follicle. These receptors, which are rapidly adapting, detect movement on the surface of the body. Ruffini end organs are found in the skin and deeper structures, including the joint capsules. These receptors, which have multibranched encapsulated endings, have very little adaptive capacity and are important for signaling continuous states of deformation, such as heavy and continuous touch and pressure since they are sensitive to skin stretch.\(^2\)

Almost all the specialized touch receptors, such as Merkel disks, Meissner corpuscles, hair follicle end organs, pacinian corpuscles, and Ruffini end organs, transmit their signals in large myelinated nerve fibers (i.e., types A\(\alpha\), A\(\beta\)) that have transmission velocities ranging from 30 to 70 m/second.\(^1\) Most free nerve endings transmit signals by way of small myelinated fibers (i.e., type A\(\delta\)) with conduction velocities of 5 to 30 m/second.\(^1\)

The sensory information for tactile sensation enters the spinal cord through the dorsal roots of the spinal nerves. All tactile sensation that requires rapid transmission is transmitted through the discriminative pathway to the thalamus by way of the medial lemniscus. This includes touch sensation requiring a high degree of localization or fine gradations of intensity, vibratory sensation, and sensation that signals movement against the skin. In addition to the ascending discriminative pathway, tactile sensation uses the more primitive and crude anterolateral pathway. The afferent axons that carry tactile information up the dorsal columns have many branches or collaterals, and some of these synapse in the dorsal horn near the level of dorsal root entry. After several synapses, axons are projected up both sides of the anterolateral aspect of the spinal cord to the thalamus. Few fibers travel all the way to the thalamus. Most synapse on reticular formation neurons that then send their axons on toward the thalamus. The lateral nuclei of the thalamus are capable of contributing a crude, poorly localized sensation from the opposite side of the body. From the thalamus, some projections travel to the somatosensory cortex, especially to the side opposite the stimulus.

Due to multiple routes, total destruction of the anterolateral pathway seldom occurs. The only time this crude alternative system becomes essential is when the discriminative pathway is damaged. Then, despite projection of the anterolateral aspect of the spinal cord to the thalamus. Few fibers travel all the way to the thalamus. Most synapse on reticular formation neurons that then send their axons on toward the thalamus. The lateral nuclei of the thalamus are capable of contributing a crude, poorly localized sensation from the opposite side of the body. From the thalamus, some projections travel to the somatosensory cortex, especially to the side opposite the stimulus.

### Thermal Sensation

Thermal sensation is discriminated by three types of receptors—cold, warmth, and pain. The cold and warmth receptors are located immediately under the skin at discrete but separate points. In some areas, there are more cold receptors than warmth receptors. For example, the lips have 15 to 25 cold receptors per square centimeter, compared with 3 to 5 in the same-sized area of the finger.\(^1\) Different gradations of heat and cold reception result from the relative degrees of
stimulation of the different types of nerve endings. Warmth receptors respond proportionately to increases in skin temperature between 32°C and 48°C and cold receptors to temperatures between 10°C and 40°C.\textsuperscript{4} The thermal pain receptors are stimulated only by extremes of temperature such as “freezing cold” (temperatures below 10°C) and “burning hot” (temperatures above 48°C) sensations.\textsuperscript{4} Thermal receptors respond rapidly to sudden changes in temperature and then adapt over the next few minutes. They do not adapt completely, however, but continue to respond to steady states of temperature. For example, the sensation of heat one feels on entering a tub of hot water or the extreme degree of cold experienced when going outside on a cold day is the initial response to a change in temperature, followed by an adaptation in which one gets accustomed to the temperature change but still feels the heat or cold because the receptors have not adapted completely.

Thermal afferents, with receptive thermal endings in the skin, send their central axons into the segmental dorsal horn of the spinal cord. On entering the dorsal horn, thermal signals are processed by second-order input association neurons. These association neurons activate projection neurons whose axons then cross to the opposite side of the cord and ascend in the multisynaptic, slow-conducting anterolateral system to the opposite side of the brain. Thalamic and cortical somatosensory regions for temperature are mixed with those for tactile sensibility.

Conduction of thermal information through peripheral nerves is quite slow compared with the rapid tactile afferents that travel through the discriminative system. If a person places a foot in a tub of hot water, the tactile sensation occurs well in advance of the burning sensation. The foot has been removed from the hot water by the local withdrawal reflex well before the excessive heat is perceived by the forebrain. Local anesthetic agents block the small-diameter afferents that carry thermal sensory information before they block the large-diameter axons that carry discriminative touch information.

**Position Sensation**

Position sense refers to the sense of limb and body movement and position without using vision. It is mediated by input from proprioceptive receptors (muscle spindle receptors and Golgi tendon organs) found primarily in muscles, tendons, and joint capsules. There are two submodalities of proprioception—the stationary or static component (limb position sense) and the dynamic aspects of position sense (kinesthesia). Both of these depend on constant transmission of information to the CNS regarding the degree of angulation of all joints and the rate of change in angulation. In addition, stretch-sensitive receptors in the skin (Ruffini end organs, pacinian corpuscles, and Merkel cells) also signal postural information. Signals from these receptors are processed through the dorsal column–medial lemniscus pathway. They transmit signals from the periphery to the cerebral cortex, which are then processed in the thalamus before reaching the cerebral cortex. Lesions affecting the posterior column impair position sense. The vestibular system also plays an essential role in position sense.

### Clinical Assessment of Somatosensory Function

Performing a neurologic assessment of somatosensory function includes testing the integrity of spinal segmental nerves. A pinpoint pressed against the skin of the sole of the foot that results in a withdrawal reflex, and a complaint of skin pain confirms the functional integrity of the afferent terminals in the skin, the entire pathway through the peripheral nerves of the foot, leg, and thigh to the sacral (S1) dorsal root ganglion and through the dorsal root into the spinal cord segment.

It confirms that the somatosensory input association cells receiving this information are functioning and that the reflex circuitry of the cord segments (L5 to S2) is functioning. Also, the lower motor neurons of the L4 to S1 ventral horn can be considered operational, and their axons through the ventral roots, the mixed peripheral nerve, and the motor neuron to the muscles producing the withdrawal response can be considered intact and functional. The communication between the lower motor neuron and the muscle cells is functional, and these muscles have normal responsiveness and strength.

Testing is done at each segmental level, or dermatome, moving upward along the body and neck from coccygeal segments through the high cervical levels to test the functional integrity of all the spinal nerves. Similar dermatomes cover the face and scalp, and these, although innervated by cranial segmental nerves, are tested in the same manner.

Observation of a normal withdrawal reflex rules out peripheral nerve disease, disorders of the dorsal root and ganglion, diseases of the neuromuscular junction, and severe muscle diseases. Normal reflex function also indicates that many major descending CNS tracts are functioning within normal limits. If the person is able to report the pinprick sensation and accurately identify its location, many ascending systems through much of the spinal cord and brain also are functioning normally, as are basic intellect and speech mechanisms.

The integrity of the discriminative dorsal column–medial lemniscus pathway compared with the anterolateral tactile pathways is tested with the person’s eyes closed by gently brushing the skin with a wisp of cotton, touching an area with one or two sharp points, touching corresponding parts of the body on each side simultaneously or in random sequence, and passively bending the person’s finger one way and then another in random order. If only the anterolateral pathway is functional, the tactile threshold is markedly elevated, two-point discrimination and proprioception are missing, and the person has difficulty discriminating which side of the body received stimulation.

### IN SUMMARY

The somatosensory component of the nervous system provides an awareness of body sensations such as touch, temperature, position sense, and pain. There are three primary levels of neural integration in the somatosensory system: the sensory units containing the sensory receptors, the ascending...
pathways, and the central processing centers in the thalamus and cerebral cortex. A sensory unit consists of a single dorsal root ganglion neuron, its receptors, and its central axon that terminates in the dorsal horn of the spinal cord or medulla. The part of the body innervated by the somatosensory afferent neurons of one set of dorsal root ganglia is called a dermatome. Ascending pathways include the discriminative pathway, which crosses at the base of the medulla, and the anterolateral pathway, which crosses within the first few segments of entering the spinal cord. Perception, or the final processing of somatosensory information, involves centers in the thalamus and somatosensory cortex. In the thalamus, the sensory information is crudely localized and perceived. The full localization, discrimination of the intensity, and interpretation of the meaning of the stimuli require processing by the somatosensory cortex. The sensory homunculus reflects the density of cortical neurons devoted to sensory input from afferents in corresponding peripheral areas.

The tactile system relays the sensations of touch, pressure, and vibration. It uses two anatomically separate pathways to relay touch information to the opposite side of the forebrain: the dorsal column discriminative pathway and the anterolateral pathway. Delicate touch, vibration, position, and movement sensations use the discriminative pathway to reach the thalamus, where third-order relay occurs to the primary somatosensory strip of the parietal cortex. Crude tactile sensation is carried by the bilateral slow-conducting anterolateral pathway. Temperature sensations of warm—hot and cool—cold are the result of stimulation to thermal receptors of sensory units projecting to the thalamus and cortex through the anterolateral system on the opposite side of the body. Proprioception is the sense of limb and body movement and position without using vision. Proprioceptive information is processed through the rapid-transmitting dorsal column–medial lemniscus pathway. Testing of the ipsilateral dorsal column (discriminative touch) system or the contralateral temperature projection system permits diagnostic analysis of the level and extent of damage in the somatosensory pathways.

The International Association for the Study of Pain defines pain as an “unpleasant sensory and emotional experience associated with actual and potential tissue damage.” Pain is when a person reacts to a stimulus by removing the trigger causing the noxious stimulation. It is generally known that the concept of pain perception and reaction to pain can be separated. Distress of pain is more heavily influenced by the reaction to pain than by actual pain intensity. Anxiety, culture, gender, age, past experience, and expectations about pain relief can influence the person’s reaction to pain. Pain involves anatomic structures and physiologic behaviors, as well as psychological, social, cultural, and cognitive factors.

Pain is a common symptom that varies widely in intensity and spares no age group. When pain is extremely severe, it disrupts a person’s behavior and can consume all of a person’s attention. It can be equally devastating for infants and children, young and middle-aged adults, as well as adults over 65 years of age. Both acute pain and chronic pain can be major health problems. Pain is the most common symptom for which people seek medical attention. Acute pain often results from injury, surgery, or invasive medical procedures. It also can be a presenting symptom for some infections (e.g., pharyngitis, appendicitis, otitis media). Chronic pain can be symptomatic of a wide range of health problems (e.g., arthritis, back injury, cancer). Approximately one in four Americans experienced a daylong bout of pain in the last month; one in ten Americans says his or her pain lasted longer than a year.

The experience of pain depends on both sensory perception and stimulation. The perception of pain can be heavily influenced by the endogenous analgesia system that modulates the sensation of pain. This can be illustrated by the phenomenon of soldiers injured in battle or athletes injured during a game who do not perceive major injuries as painful until they leave the battlefield or the game and begin to feel the manifestations of their injuries. Sensory stimulation refers to the processes by which a person experiences pain. An example of this would be nociceptive or neuropathic pain. Additionally if people are given multiple types of pain relief (both pharmacological and nonpharmacological), it has been found that 70% to 90% of people with cancer say they are satisfied with their pain control.

Pain can be either nociceptive or neuropathic in origin. The receptors for pain (nociceptors) are free nerve endings. When nociceptors are activated in response to actual or impending tissue injury, nociceptive pain is the consequence. Neuropathic pain arises from direct injury or dysfunction of the sensory axons of peripheral or central nerves. Tissue and nerve injury can result in a wide range of symptoms. These include pain from noninjurious stimuli to the skin (allodynia), extreme sensitivity to pain (hyperalgesia), and the absence of pain from stimuli that normally would be painful (analgesia). The latter, although not painful, can be extremely serious (e.g., in diabetic persons with peripheral neuropathy) because the normally protective early warning system for the presence of tissue injury is absent.

PAIN

After completing this, you should be able to meet the following objectives:

- Discuss the differences among the specificity, pattern, gate control, and neuromatrix theories of pain.
- Discuss the difference between the Aδ- and C-fiber neurons in the transmission of pain information.
- Explain the transmission of pain signals with reference to the neospinothalamic, paleospinothalamic, and reticulospinal pathways, including the role of chemical mediators and factors that modulate pain transmission.
Pain Theories

Traditionally, two theories were offered to explain the physiologic basis for the pain experience—specificity theory and pattern theory. Specificity theory regards pain as a separate sensory modality evoked by the activity of specific receptors that transmit information to pain centers or regions in the forebrain where pain is experienced. This theory describes how painful a specific acute injury is predicted to be. However, this theory does not encompass the person’s feelings of how the pain feels to him or her, or how the person has handled, or even experienced, pain in the past. Pattern theory is comprised of a collective group of theories. It proposes that pain receptors share endings or pathways with other sensory modalities but that different patterns of activity (i.e., spatial or temporal) of the same neurons can be used to signal painful and nonpainful stimuli. For example, light touch applied to the skin would produce the sensation of touch through low-frequency firing of the receptor. On the other hand, intense pressure would produce pain through high-frequency firing of the same receptor. Both specificity and pattern theories focus on the neurophysiologic basis of pain, and both probably apply. Specific nociceptive afferents have been identified. However, almost all afferent stimuli, if driven at a very high frequency, can be experienced as painful.

Gate control theory, a modification of specificity theory, was proposed by Melzack and Wall in 1965 to meet the challenges presented by the pattern theories. This theory postulated the presence of neural gating mechanisms at the segmental spinal cord level to account for interactions between pain and other sensory modalities. The original gate control theory proposed a spinal cord–level network of transmission or projection cells and internuncial neurons that inhibits the transmission cells, forming a segmental-level gating mechanism that could block projection of pain information to the brain.

According to the gate control theory, the internuncial neurons involved in the gating mechanism are activated by large-diameter, faster-propagating fibers that carry tactile information. The simultaneous firing of the large-diameter touch fibers has the potential for blocking the transmission of impulses from the small-diameter myelinated and unmyelinated pain fibers. Pain therapists have long known that pain intensity can be temporarily reduced during active tactile stimulation. For example, repeated sweeping of a soft-bristled brush on the skin (i.e., brushing) over or near a painful area may result in pain reduction for several minutes to several hours.

Pain modulation is now known to be a much more complex phenomenon than that proposed by the original gate control theory. Tactile information is transmitted by small- and large-diameter fibers. Major interactions between sensory modalities, including the so-called gating phenomenon, occur at several levels of the CNS rostral to the input segment. Perhaps the most puzzling aspect of locally applied stimuli, such as brushing, that can block the experience of pain is the relatively long-lasting effect (minutes to hours) of such treatments. This prolonged effect has been difficult to explain on the basis of specificity theories, including the gate control theory. Other important factors include the effect of endogenous opioids and their receptors at the segmental and brain stem level, descending feedback modulation, altered sensitivity, learning, and culture. Despite this complexity, the Melzack and Wall theory has served a useful purpose. It sparked interest in pain and stimulated research and clinical activity related to the pain-modulating systems.

Melzack developed the neuromatrix theory to address further the brain’s role in pain as well as the multiple dimensions and determinants of pain. The neuromatrix theory is particularly useful in understanding chronic pain and phantom limb pain, in which there is not a simple one-to-one relationship between tissue injury and pain experience. The neuromatrix theory proposes that the brain contains a widely distributed neural network, called the body–self neuromatrix, that contains somatosensory, limbic, and thalamocortical components. Genetic and sensory influences determine the synaptic architecture of an individual’s neuromatrix that integrates multiple sources of input and yields the neurosignature pattern that evokes the sensory, affective, and cognitive dimensions of pain experience and behavior. These multiple sources include:

- Somatosensory inputs
- Other sensory inputs affecting interpretation of the situation
- Phasic and tonic inputs from the brain addressing such things as attention, expectation, culture, and personality
- Intrinsic neural inhibitory modulation
- Various components of stress regulation systems

The neuromatrix theory may open entire new areas of research, such as an understanding of the role that cortisol plays in chronic pain, the effect estrogen has on pain mediated through the release of peripheral cytokines, and the reported increase in chronic pain that occurs with age.

Pain Mechanisms and Pathways

Pain usually is viewed in the context of tissue injury. The term nociception, which means “pain sense,” comes from the Latin word nocere, “to injure.” Nociceptive stimuli are objectively defined as stimuli of such intensity that they cause, or are close to causing, tissue damage. The withdrawal reflex (e.g., the reflexive withdrawal of a body part from a tissue-damaging stimulus) is used to determine when a stimulus is nociceptive. Stimuli used include pressure from a sharp object, strong electric current to the skin, or application of heat or cold applied to skin. At low levels of intensity, these noxious stimuli do activate nociceptors (pain receptors), but are perceived as painful only when the intensity reaches a level where tissue damage occurs or is imminent.

The mechanisms of pain are many and complex. As with other forms of somatosensation, the pathways are composed of first-, second-, and third-order neurons (Fig. 18.7).
greater conduction velocities, transmitting impulses at a rate of 6 to 30 m/second. The C fibers are the smallest of all peripheral nerve fibers; they transmit impulses at the rate of 0.5 to 2.0 m/second. Pain conducted by Aδ fibers traditionally is called fast pain and typically is elicited by mechanical or thermal stimuli. C-fiber pain often is described as slow-wave pain because it is slower in onset and longer in duration. It is incited by chemical stimuli or by persistent mechanical or thermal stimuli. The slow postexcitatory potentials generated in C fibers are responsible for central sensitization to chronic pain.

**Stimulation of Nociceptors.** Unlike other sensory receptors, nociceptors respond to several forms of stimulation, including mechanical, thermal, and chemical. Some receptors respond to a single type of stimuli (mechanical or thermal) and others, called polymodal receptors, respond to all three types of stimuli (mechanical, thermal, and chemical). Mechanical stimuli can arise from intense pressure applied to skin or from the violent contraction or extreme stretch of a muscle. Both extremes of heat and cold can stimulate nociceptors. Chemical stimuli arise from a number of sources, including tissue trauma, ischemia, and inflammation. A wide range of chemical mediators are released from injured and inflamed tissues, including hydrogen and potassium ions, prostaglandins, leukotrienes, histamine, bradykinin, acetycholine, and serotonin. These chemical mediators produce their effects by directly stimulating nociceptors or sensitizing them to the effects of nociceptive stimuli, perpetuating the inflammatory responses that lead to the release of chemical agents that act as nociceptive stimuli, or inciting neurogenic reflexes that increase the response to nociceptive stimuli. For example, bradykinin, histamine, serotonin, and potassium activate and also sensitize nociceptors. Adenosine triphosphate, acetylcholine, and platelets act alone or in concert to sensitize nociceptors through other chemical agents such as prostaglandins. Aspirin and other nonsteroidal anti-inflammatory drugs (NSAIDs) are effective in controlling pain because they block the enzyme needed for prostaglandin synthesis.

Nociceptive stimulation that activates C fibers can cause a response known as neurogenic inflammation that produces vasodilation and an increased release of chemical mediators to which nociceptors respond. The C-fiber mechanism is thought to be mediated by a dorsal root neuron reflex that produces retrograde transport and release of chemical mediators, which in turn causes increasing inflammation of peripheral tissues. This reflex can set up a vicious cycle, which has implications for persistent pain and hyperalgesia.

**Mediators in the Spinal Cord.** In the spinal cord, the transmission of impulses between the nociceptive neurons and the dorsal horn neurons is mediated by chemical neurotransmitters released from central nerve endings of the nociceptive neurons. Some of these neurotransmitters are amino acids (e.g., glutamate), others are amino acid derivatives.
(e.g., norepinephrine), and still others are low-molecular-weight peptides composed of two or more amino acids. The amino acid glutamate is a major excitatory neurotransmitter released from the central nerve endings of the nociceptive neurons. Substance P, a neuropeptide, also is released in the dorsal horn by C fibers in response to noxious stimulation. Substance P elicits slow excitatory potentials in dorsal horn neurons. Unlike glutamate, which confines its action to the immediate area of the synaptic terminal, some neuropeptides released in the dorsal horn can diffuse some distance because they are not inactivated by reuptake mechanisms. In persistent pain, this may help to explain the excitability and unlocalized nature of many painful conditions. Neuropeptides such as substance P also appear to prolong and enhance the action of glutamate. If these neurotransmitters are released in large quantities or over extended periods, they can lead to secondary hyperalgesia, a condition in which the second-order neurons are overly sensitive to low levels of noxious stimulation.

**KEY POINTS**

**PAIN SENSATION**

- The pathway for fast, sharply discriminated pain that moves directly from the receptor to the spinal cord using myelinated Aδ fibers and from the spinal cord to the thalamus using the neospinothalamic tract
- The pathway for slow, continuously conducted pain that is transmitted to the spinal cord using unmyelinated C fibers and from the spinal cord to the thalamus using the more circuitous and slower-conducting paleospinothalamic tract

**Spinal Cord Circuitry and Pathways**

On entering the spinal cord through the dorsal roots, the pain fibers bifurcate and ascend or descend one or two segments before synapsing with association neurons in the dorsal horn. From the dorsal horn, the axons of association projection neurons cross through the anterior commissure to the opposite side and then ascend upward in the previously described neospinothalamic and paleospinothalamic pathways (Fig. 18.8).

The faster-conducting fibers in the neospinothalamic tract are associated mainly with the transmission of sharp–fast pain information to the thalamus. In the thalamus, synapses are made and the pathway continues to the contralateral parietal somatosensory area to provide the precise location of the pain.

The paleospinothalamic tract is a slower-conducting, multisynaptic tract concerned with the diffuse, dull, aching, and unpleasant sensations that commonly are associated with chronic and visceral pain. This information travels through the small, unmyelinated C fibers. Fibers of this system also project up the contralateral anterolateral pathway to terminate in several thalamic regions, including the intralaminar nuclei, which project to the limbic system. It is associated with the emotional or affective–motivational aspects of pain. Spinoreticular fibers from this pathway project bilaterally to the reticular formation of the brain stem. This component of the paleospinothalamic system facilitates avoidance reflexes at all levels. It also contributes to an increase in the electroencephalographic activity associated with alertness and indirectly influences hypothalamic functions associated with sudden alertness, such as increased heart rate and blood pressure. This may explain the tremendous arousal effects of certain pain stimuli.

Dorsal horn (second-order) neurons are divided primarily into two types: wide–dynamic-range (WDR) neurons that respond to different low-intensity stimuli and nociceptive-specific neurons that respond only to noxious or nociceptive stimuli. When stimuli are increased to a noxious level, the WDR neurons respond more intensely. After more severe damage to peripheral sensory afferents, Aδ and C fibers respond more intensely as they are increasingly stimulated. When C fibers are repetitively stimulated at a rate of once per second, each stimulus produces a progressively increased response from the WDR neurons. This phenomenon of amplification of transmitted signals has been called windup and may explain why pain sensation appears to increase with repeated stimulation. Windup and sensitization of dorsal horn neurons have implications for appropriate and early, or even preemptive, pain therapy to avoid the possibility of spinal cord neurons becoming hypersensitive or subject to firing spontaneously.

**Brain Centers and Pain Perception**

Information from tissue injury is carried from the spinal cord to brain centers in the thalamus where the basic sensation of hurtfulness, or pain, occurs (Fig. 18.9). In the neospinothalamic system, interconnections between the lateral thalamus and the somatosensory cortex are necessary to add precision, discrimination, and meaning to the pain sensation. The paleospinothalamic system projects diffusely from the intralaminar nuclei of the thalamus to large areas of the limbic cortex. These connections probably are associated with the hurtfulness and the mood-altering and attention-narrowing effect of pain.

Research using magnetoencephalography has demonstrated cortical representation of pain sensation in humans and has shown that it is very effective when combined with structural imaging. In healthy adults, nociceptive Aδ afferent stimulation is related to activation in the contralateral primary somatosensory cortex in the parietal lobe, whereas C afferent stimulation is related to activation of the secondary somatosensory cortices and the anterior cingulated cortex, which is part of the limbic system.

**Central Pathways for Pain Modulation**

A major advance in understanding pain was the discovery of neuroanatomic pathways that arise in the midbrain and brain stem, descend to the spinal cord, and modulate ascending pain impulses. One such pathway begins in an area of the midbrain called the periaqueductal gray (PAG) region. Through research it was found that electrical stimulation of the midbrain PAG regions produced a state of analgesia that lasted
Disorders of Neural Function

called the nucleus raphe magnus (NRM). The axons of these NRM neurons project to the dorsal horn of the spinal cord, where they terminate in the same layers as the entering primary pain fibers (see Fig. 18.8). Serotonin has been identified as a neurotransmitter in the NRM medullary nuclei. It has been shown that tricyclic antidepressant drugs, such as amitriptyline, which enhance the effects of serotonin by blocking its presynaptic uptake, have been found to be effective in the management of certain types of chronic pain. The discovery that norepinephrine can block pain transmission led to studies directed at the combined administration of opioids and clonidine, a central-acting \( \alpha \)-adrenergic agonist, for pain relief.

for many hours. Subsequently, opioid receptors were found to be highly concentrated in this and other regions of the CNS where electrical stimulation produced analgesia. Because of these findings, the PAG area of the midbrain often is referred to as the analgesia system.

The PAG area receives input from widespread areas of the CNS, including the cerebral cortex, hypothalamus, brain stem reticular formation, and spinal cord by way of the paleospinothalamic and neospinothalamic tracts. This region is intimately connected to the limbic system, which is associated with emotional experience. The neurons of the PAG have axons that descend into an area in the rostral medulla called the nucleus raphe magnus (NRM). The axons of these NRM neurons project to the dorsal horn of the spinal cord, where they terminate in the same layers as the entering primary pain fibers (see Fig. 18.8). Serotonin has been identified as a neurotransmitter in the NRM medullary nuclei. It has been shown that tricyclic antidepressant drugs, such as amitriptyline, which enhance the effects of serotonin by blocking its presynaptic uptake, have been found to be effective in the management of certain types of chronic pain. The discovery that norepinephrine can block pain transmission led to studies directed at the combined administration of opioids and clonidine, a central-acting \( \alpha \)-adrenergic agonist, for pain relief.

FIGURE 18.8 Primary pain pathways. The transmission of incoming nociceptive impulses is modulated by dorsal horn circuitry that receives input from primary touch receptors and from descending pathways that involve the limbic cortical systems (orbital frontal cortex, amygdala, and hypothalamus), the periaqueductal endogenous analgesic center in the midbrain, pontine noradrenergic neurons, and the NRM in the medulla. Dashed lines indicate inhibition or modulation of pain transmission by dorsal horn projection neurons. (RAS, reticular activating system.)
proenkephalin peptides are present in areas of the spinal cord and PAG that are related to perception of pain, in the hippocampus and other areas of the brain that modulate emotional behavior, in structures in the basal ganglia that modulate motor control, and in brain stem neurons that regulate autonomic nervous system responses.

Although the endogenous opioid peptides appear to function as neurotransmitters, their full significance in pain control and other physiologic functions is not completely understood. Laboratory studies, although somewhat inconsistent, have found that opioid agonists inhibit calcium channels in dorsal root and trigeminal ganglion neurons as well as on primary afferent neurons. Because it is calcium ions that cause neurotransmitter release at the synapse, such calcium blockage would inhibit synaptic transmission of pain impulses. The characterization of receptors that bind the endogenous opioid peptides is important in understanding the mechanisms of pain control. The identification of these receptors has facilitated a more thorough understanding of the actions of available opioid drugs, such as morphine. It also has facilitated ongoing research into the development of newer preparations, including 24-hour dispensing medications, dermal patches, and intravenous pumps that are self-administered according to perceived need.

**Pain Threshold and Tolerance**

Pain threshold and tolerance affect a person’s response to a painful stimulus. Pain threshold is the point at which a stimulus is perceived as painful. Pain tolerance is the total pain experience. It is defined as a lesser “response to a drug due to repeated drug administration.”17 Psychological, familial, cultural, and environmental factors significantly influence the amount of pain a person is willing to tolerate. Separation and identification of the role of each of these two aspects of pain continue to pose fundamental problems for the pain management team.

**Types of Pain**

Pain can be classified according to duration (acute or chronic), location (cutaneous or deep and visceral), and site of referral. Classification based on associated medical diagnosis (e.g., surgery, trauma, cancer, sickle cell disease, fibromyalgia) is also very useful in planning appropriate pain management interventions.

**Acute and Chronic Pain**

The most widely accepted classification of pain is according to its duration. Pain research emphasizes the importance of differentiating acute pain from chronic pain. The diagnosis and therapy for each is distinctive because they differ in cause, function, mechanisms, and psychological sequelae (Table 18.1).

Traditionally, the distinction between acute and chronic pain has relied on a single continuum of time with some interval (e.g., 6 months). Some conditions such as osteoarthritis exhibit dimensions of both acute and chronic pain.
Acute Pain. Acute pain is pain that is elicited by injury to body tissues and activation of nociceptive stimuli at the site of local tissue damage. It is generally of short duration and tends to resolve when the underlying pathologic process has resolved. Acute pain’s purpose is to serve as a warning system. It alerts a person to the existence of actual or impending tissue damage and prompts a search for medical help. The pain’s location, radiation, intensity, and duration, as well as those factors that aggravate or relieve it, provide essential diagnostic clues.

Interventions that alleviate the pain usually relieve other concomitant problems such as anxiety and musculoskeletal spasms. Inadequately treated pain can provoke physiologic responses that alter circulation and tissue metabolism and produce physical manifestations, such as tachycardia, reflective of increased sympathetic activity. Inadequately treated acute pain tends to decrease mobility and respiratory movements such as deep breathing and coughing to the extent that it may complicate or delay recovery.

Chronic Pain. Chronic pain is pain that persists longer than might be reasonably expected after an inciting event. In addition, it is sustained by factors that are both pathologically and physically remote from the originating cause. Chronic pain can continue for years and years. Chronic pain can be quite variable. It may be unrelenting and extremely severe, as in metastatic bone pain. It can be relatively continuous with or without periods of escalation, as with some forms of back pain. Some conditions with recurring episodes of acute pain are particularly problematic because they have characteristics of both acute and chronic pain. These include the pain associated with sickle cell crisis or migraine headaches.

Chronic pain is a leading cause of disability. Unlike acute pain, persistent chronic pain usually serves no useful function. To the contrary, it imposes physiologic, psychological, familial, and economic stresses and may exhaust a person’s resources. In contrast to acute pain, psychological and environmental influences may play an important role in the development of behaviors associated with chronic pain.

The biologic factors that influence chronic pain include peripheral mechanisms, peripheral–central mechanisms, and central mechanisms. Peripheral mechanisms result from persistent stimulation of nociceptors and are mostly involved with chronic musculoskeletal, visceral, and vascular disorders. Peripheral–central mechanisms are related to abnormal function of the peripheral and central portions of the somatosensory system, such as those resulting from partial or complete loss of descending inhibitory pathways or spontaneous firing of regenerated nerve fibers. They include conditions such as causalgia, phantom limb pain, and postherpetic neuralgia. Central pain mechanisms are associated with disease or injury of the CNS and characterized by burning, aching, hyperalgesia, dysesthesia, and other abnormal sensations. Central pain is associated with conditions such as thalamic lesions (thalamic pain), spinal cord injury, surgical interruption of pain pathways, and multiple sclerosis.

People with chronic pain may not exhibit the somatic, autonomic, or affective behaviors often associated with acute pain. As painful conditions become prolonged and
Cutaneous and Deep Somatic Pain

Pain can also be classified according to its location. Cutaneous pain arises from superficial structures. It is a sharp pain with a burning quality that may be abrupt or slow in onset. It can be localized accurately and may be distributed along the dermatomes. Due to an overlap of nerve fiber distribution between the dermatomes, the boundaries of pain frequently are not as clear-cut as dermatome diagrams indicate.

Deep somatic pain originates in deep body structures (e.g., periosteum, muscles, tendons, joints, and blood vessels). It is more diffuse than cutaneous pain. Various stimuli, such as strong pressure exerted on bone, ischemia to a muscle, and tissue damage, can produce deep somatic pain. An example of this is the pain that a person experiences from a sprained ankle. Radiation of pain from the original site of injury can occur.

Visceral Pain

Visceral pain has its origin in the visceral organs and is one of the most common pains produced by disease. While similar to somatic pain in many ways, both the neurologic mechanisms and the perception of visceral pain differ from somatic pain. One of the most important differences between surface pain and visceral pain is the type of damage that causes pain. Strong contractions, distention, or ischemia affecting the walls of the viscera can induce severe pain. There is a low density of nociceptors in the viscera compared with the skin. There is functional divergence of visceral input within the CNS, which occurs when many second-order neurons respond to a stimulus from a single visceral afferent.

Visceral nociceptive afferents from the thorax and abdomen travel along the cranial and spinal nerve pathways of the autonomic nervous system. For many years it was believed that the spinothalamic and spinoreticular tracts carried visceral nociceptive information. Identification of new pathways is sometimes quite important clinically for determining new pain management techniques.

Referred Pain

Referred pain is pain that is perceived at a site different from its point of origin but innervated by the same spinal segment. It is hypothesized that visceral and somatic afferent neurons converge on the same dorsal horn projection neurons (Fig. 18.10). For this reason, it can be difficult for the brain to correctly identify the original source of pain. Pain that originates in the abdominal or thoracic viscera is diffuse and poorly localized and often perceived at a site far removed from the affected area. For example, the pain associated with myocardial infarction commonly is referred to the left arm, neck, and chest, which may delay diagnosis and treatment of a potentially life-threatening condition.

Referred pain may arise alone or concurrent with pain located at the origin of the noxious stimuli. This lack of correspondence between the location of the pain and the location of the painful stimuli can make diagnosis difficult. Although the term referred usually is applied to pain that originates in the viscera and is experienced as if originating from the body wall, it also may be applied to pain that arises from somatic structures. For example, pain referred to the chest wall could be caused by nociceptive stimulation of the peripheral portion of the diaphragm, which receives somatosensory innervation from the intercostal nerves. An understanding of pain referral is of great value in diagnosing illness. The typical pattern of pain referral can be derived from our understanding that the afferent neurons from visceral or deep somatic tissue enter the spinal cord at the same level as the afferent neurons from the cutaneous areas to which the pain is referred (Fig. 18.11).

The sites of referred pain are determined embryologically with the development of visceral and somatic structures that share the same site for entry of sensory information into the CNS and then move to more distant locations. For example, a person with peritonitis may complain of pain in the shoulder. Internally, there is inflammation of the peritoneum that lines the central part of the diaphragm. In the embryo, the diaphragm originates in the neck, and its central portion is innervated by the phrenic nerve, which enters the cord at the level of the third to fifth segments (C3 to C5). As the fetus develops, the diaphragm descends to its adult position between the thoracic and abdominal cavities while maintaining its embryonic pattern of innervation. Thus, fibers that enter the spinal cord at the C3 to C5 levels carry information from both the neck area and the diaphragm, and the diaphragmatic pain
is interpreted by the forebrain as originating in the shoulder or neck area.

Although the visceral pleura, pericardium, and peritoneum are said to be relatively free of pain fibers, the parietal pleura, pericardium, and peritoneum do react to nociceptive stimuli. Visceral inflammation can involve parietal and somatic structures, and this may give rise to diffuse local or referred pain. For example, when the parietal peritoneum is irritated from appendicitis, it typically gives rise to pain directly over the inflamed area in the lower right quadrant, evoking pain referred to the umbilical area.

Muscle spasm, or guarding, occurs when somatic structures are involved. Guarding is a protective reflex rigidity. Its purpose is to protect the affected body parts (e.g., an abscessed appendix or a sprained muscle). This protective guarding may cause blood vessel compression and give rise to the pain of muscle ischemia, causing local and referred pain.

**KEY POINTS**

**TYPES OF PAIN**

- Pain can be classified according to duration (acute or chronic), location (cutaneous or deep and visceral), and site of referral.
- Acute pain is a self-limiting pain that lasts less than 6 months.
- Chronic pain is persistent pain that lasts longer than 6 months, lacks the autonomic and somatic responses associated with acute pain, and is accompanied by loss of appetite, sleep disturbances, depression, and other debilitating responses.

**Assessment of Pain**

Careful assessment of pain assists clinicians in diagnosing, managing, and relieving the person’s pain. Assessment includes such things as the nature, severity, location, and radiation of the pain. As with other disease states, eliminating the cause of the pain is preferable to simply treating the symptom of pain. A careful history often provides information about the triggering factors (i.e., injury, infection, or disease) and the site of nociceptive stimuli (i.e., peripheral receptor or visceral organ). A comprehensive pain history should include:

- Pain onset
- Description, localization, radiation, intensity, quality, and pattern of the pain
- Anything that relieves or exacerbates it
- The person’s personal reaction to the pain

Unlike many other bodily responses, such as temperature and blood pressure, the nature, severity, and distress of pain cannot be measured objectively. To overcome this problem, various methods have been developed for quantifying a person’s pain based on the person’s report. They include numeric pain intensity, visual analog, and verbal descriptor scales. Most pain questionnaires assess a single aspect of pain such as pain intensity. For example, a numeric pain intensity scale asks people to select which number best represents the intensity of their pain, where 0 represents no pain and 10 represents the most intense pain imaginable. A visual analog scale also can be used. It is a straight line, often 10 cm in length, with a word description (e.g., “no pain” and “the most intense pain imaginable”) at each of the ends of the line representing the continuum of pain intensity. People are asked to choose a point on the continuum that represents the intensity of their pain. The response can be quantified by measuring the line to determine the distance of the mark, measured in millimeters, from the “no pain” end of the line. Verbal descriptor scales consist of several numerically ranked choices of words such as none = 0, slight = 1, mild = 2, moderate = 3, and severe = 4. The word chosen is used to determine the numeric representation of pain severity on an ordinal scale.
Management of Pain

The therapeutic approaches to managing acute and chronic pain differ markedly. In acute pain, therapy is directed at providing pain relief by interrupting the nociceptive stimulus. Because the pain is self-limited, in that it resolves as the injured tissues heal, long-term therapy usually is not needed. Chronic pain management is much more complex and is based on multiple considerations, including life expectancy.

Managing Acute Pain

Acute pain should be aggressively managed and pain medication provided before the pain becomes severe. This allows the person to be more comfortable and active and to assume a greater role in directing his or her own care. Part of the reluctance of health care workers to provide adequate relief for acute pain has been fear of addiction. However, addiction to opioid medications is thought to be virtually nonexistent when these drugs are prescribed for acute pain. Usually, less medication is needed when the drug is given before the pain becomes severe and the pain pathways become sensitized.

Managing Chronic Pain

Management of chronic pain requires early attempts to prevent pain and adequate therapy for acute bouts of pain. Specific treatment depends on the cause of the pain, the natural history of the underlying health problem, as well as the life expectancy of the person. If the organic illness causing the pain cannot be cured, then noncurative methods of pain control become the cornerstone of treatment. Treatment methods for chronic pain can include neural blockade, electrical modalities (e.g., transcutaneous electrical nerve stimulation [TENS]), physical therapy, cognitive–behavioral interventions, and nonnarcotic and narcotic medications. Nonnarcotic medications such as tricyclic antidepressants, antiseizure medications, and NSAIDs serve as useful adjuncts to opioids for the treatment of different types of chronic pain. Chronic pain is best handled by a multidisciplinary team that includes specialists in areas such as anesthesiology, nursing, physical therapy, social services, and surgery.

Cancer is a common cause of chronic pain. The goal of chronic cancer pain management should be pain alleviation and prevention. Pain control remains a significant problem despite the advances in understanding and management of pain. Analgesics, adjuvant drugs, cognitive or behavioral strategies, physical modalities, and nerve blocks are used for many forms of chronic pain. Depending on the form and stage of the cancer, other treatments such as palliative radiation, antineoplastic therapies, and palliative surgery may help to control the pain. The World Health Organization has created an analgesic ladder for cancer pain that assists clinicians in choosing the appropriate analgesic.18

Nonpharmacologic Pain Management

A number of nonpharmacologic methods of pain control often are used in pain management. These include cognitive–behavioral interventions, physical agents such as heat and cold, and electroanalgesia. Often these methods are used in addition to analgesics rather than as the only form of pain management.

Cognitive–Behavioral Interventions. Cognitive–behavioral interventions, which often are helpful for people experiencing acute as well as chronic pain, include relaxation, distraction, cognitive reappraisal, imagery, meditation, and biofeedback. If the person is having surgery or a painful procedure, it is ideal to teach these techniques before the pain begins (e.g., before surgery). If the person is already in severe pain, the use of cognitive–behavioral interventions should be based on the person’s ability to master the technique as well as his or her response to the intervention. For example, it may be a more appropriate adjunct to analgesics for a terminally ill person in severe pain to use self-selected relaxing music rather than trying to teach that person an intervention requiring more attention (e.g., meditation or cognitive reappraisal).

Relaxation is one of the best-evaluated cognitive–behavioral approaches to pain relief. The relaxation method need not be complex. Relatively simple strategies, such as slow, rhythmic breathing and brief jaw relaxation procedures, have been successful in decreasing self-reported pain and analgesic use.

Distraction (i.e., focusing a person’s attention on stimuli other than painful stimuli or negative emotions) does not eliminate pain, but it can make pain more tolerable. It may serve as a type of sensory shielding whereby attention to pain is sacrificed to pay attention to other stimuli that are easily perceived. Examples of distraction include counting, repeating phrases or poems, and engaging in activities that require concentration, such as projects, activities, work, conversation, or describing pictures. Television, adventure movies, music, and humor also can provide distraction. Cognitive reappraisal is a form of self-distraction or cognitive control in which people focus their attention on the positive aspects of the experience and away from their pain. Individuals using distraction may not appear to be in severe pain. Nonetheless, it is inappropriate to assume that a person who copes with pain by using distraction does not have pain. Prescribed analgesics should not be denied to people simply because they appear to be coping with their pain without medication. Appropriate assessment is needed to determine the person’s level of pain and what other interventions for pain may be needed.

Imagery consists of using one’s imagination to develop a mental picture. In pain management, therapeutic guided imagery (i.e., goal-directed imaging) is used. It can be used alone or in conjunction with other cognitive–behavioral interventions (e.g., relaxation or biofeedback) to develop sensory images that may decrease the perceived intensity of pain. It also can be used to lessen anxiety and reduce muscle tension. Meditation also can be used, but it requires practice and the ability to concentrate to be effective.

Biofeedback is used to provide feedback to a person concerning the current status of some body function (e.g., finger
temperature, temporal artery pulsation, blood pressure, or muscle tension). It involves a process of learning designed to make the person aware of certain of his or her own body functions for the purpose of modifying these functions at a conscious level. Interest in biofeedback increased with the possibility of using this treatment modality in the management of migraine and tension headaches or for other pain that has a muscle tension component.

Physical Agents. Heat and cold are physical agents that are used to provide pain relief. The choice of physical agent depends on the type of pain being treated and, in many cases, personal preference.

Heat has long been used to relieve pain. Heat dilates blood vessels and increases local blood flow. It also can influence the transmission of pain impulses and increase collagen extensibility. An increase in local circulation can reduce the level of nociceptive stimulation by reducing local ischemia caused by muscle spasm or tension, increase the removal of metabolites and inflammatory mediators that act as nociceptive stimuli, and help to reduce swelling and relieve pressure on local nociceptive endings. The heat sensation is carried to the posterior horn of the spinal cord and may exert its effect by modulating projection of pain transmission. It also may trigger the release of endogenous opioids. Heat also alters the viscosity of collagen fibers in ligaments, tendons, and joint structures so that they are more easily extended and can be stretched further before the nociceptive endings are stimulated. Thus, heat often is applied before therapy aimed at stretching joint structures and increasing range of motion. Care must be taken not to use excessive heat. When excessive heat is used, the heat itself becomes a noxious stimulus, which results in actual or impending tissue damage and pain. In certain conditions, the use of heat is controversial, and in some conditions (e.g., peripheral vascular disease) where increased blood flow or metabolism would be detrimental, the use of heat is contraindicated.

Like heat, the application of cold may produce a dramatic reduction in pain. Cold exerts its effect on pain through circulatory and neural mechanisms. The initial response to local application of cold is sudden local vasoconstriction. This initial vasoconstriction is followed by alternating periods of vasodilation and vasoconstriction during which the body “hunts” for its normal level of blood flow to prevent local tissue damage. The vasoconstriction is caused by local stimulation of sympathetic fibers and direct cooling of blood vessels, and the hyperemia by local autoregulatory mechanisms. In situations of acute injury, cold is used to produce vasoconstriction and prevent extravasation of blood into the tissues. Pain relief results from decreased swelling and decreased stimulation of nociceptive endings. The vasodilation that follows can be useful in removing substances that stimulate nociceptive endings.

Cold also can have a marked and dramatic effect on pain that results from the spasm-induced accumulation of metabolites in muscle. In terms of pain modulation, cold may reduce afferent activity reaching the posterior horn of the spinal cord by modulating sensory input. The application of cold is a noxious stimulus and may influence the release of endogenous opioids from the PAG area. Cold packs should be flexible to conform to body parts easily, adequately wrapped to protect the skin, and applied no more than 15 to 20 minutes at a time.

Stimulus-Induced Analgesia. Stimulus-induced analgesia is one of the oldest known methods of pain relief. Electrical stimulation methods of pain relief include TENS, electrical acupuncture, and neurostimulation. TENS refers to the transmission of electrical energy across the surface of the skin to the peripheral nerve fibers. TENS units have been developed that are convenient, easily transported, and relatively economical to use. Most are approximately the size of a deck of cards. These battery-operated units deliver an electrical current to a target site.

The system usually consists of three parts—a pair of electrodes, lead wires, and a stimulator. The electrical stimulation is delivered in a pulsed waveform that can be varied in terms of pulse amplitude, width, and rate. The type of stimulation used varies with the type of pain being treated. The physiologic pathways and an understanding of the pain mechanisms involved determine electrode placement. They may be placed on either side of a painful area, over an affected dermatome, over an affected peripheral nerve where it is most superficial, or over a nerve trunk. For example, the electrodes commonly are placed medial and lateral to the incision when treating postoperative pain.

There probably is no single explanation for the physiologic effects of TENS. Each specific type of stimulator may have different sites of action and may be explained by more than one theory. The gate control theory was proposed as one possible mechanism. According to this theory, pain information is transmitted by small-diameter Aδ and C fibers. Large-diameter afferent A fibers and small-diameter fibers carry tactile information mediating touch, pressure, and kinesthesia. TENS may function on the basis of differential firing of impulses in the large fibers that carry nonpainful information. Accordingly, increased activity in these larger fibers purportedly modulates transmission of painful information to the forebrain. TENS has the advantage that it is noninvasive, easily regulated by the person or health professional, and effective in some forms of acute and chronic pain. Its use can be taught before surgery, affording a reduction in postoperative analgesic medication and, possibly, preventing the development of persistent pain.

Acupuncture. The practice of acupuncture involves introducing needles into specific points on the surface of the body. Charts are available that describe the points of needle placement that are used to relieve pain at certain anatomic sites. In addition to needles, sometimes palpation is used. Acupuncture is widely available in pain clinics even though large, high-quality, randomized studies on the effects of acupuncture for chronic pain are not plentiful.
Neurostimulation. Neurostimulation delivers low-voltage electrical stimulation to the spinal cord or targeted peripheral nerve to block the sensation of pain. Melzack and Wall (gate theory) proposed that neurostimulation activates the body’s pain-inhibiting system. For a totally implantable system, the power source (battery) and lead(s) are surgically implanted.

Pharmacologic Treatment
Analgesics have been used for many years to relieve pain of short duration. An analgesic is a medication that acts on the nervous system to decrease or eliminate pain without inducing loss of consciousness. Analgesic drugs do not cure the underlying cause of the pain, but their appropriate use may prevent acute pain from progressing to chronic pain. Another benefit of analgesic drugs is that they enable the person to achieve mobility after surgery, for example, when exercises such as coughing and deep breathing may be required.

The ideal analgesic would be effective, nonaddictive, and inexpensive. In addition, it would produce minimal adverse effects and not affect the person’s level of consciousness. Although long-term treatment with opioids can result in opioid tolerance (i.e., more drug being needed to achieve the same effect) and physical dependence, this should not be confused with addiction. Long-term drug-seeking behavior is rare in people who are treated with opioids only during the time that they require pain relief. The unique needs and circumstances presented by each person in pain must be addressed to achieve satisfactory pain management. The use of analgesics is only one aspect of a comprehensive pain management program with acute pain, and even more so with chronic pain.

Nonnarcotic Analgesics. Common nonnarcotic oral analgesic medications include aspirin, other NSAIDs, and acetaminophen. Aspirin, or acetylsalicylic acid, acts centrally and peripherally to block the transmission of pain impulses. It also has antipyretic and anti-inflammatory properties. The action of aspirin and other NSAIDs is through the inhibition of the cyclooxygenase (COX) enzymes, which mediate the biosynthesis of prostaglandins. The NSAIDs also decrease the sensitivity of blood vessels to bradykinin and histamine, affect cytokine production by T lymphocytes, reverse vascodilation, and decrease the release of inflammatory mediators from granulocytes, mast cells, and basophils. Acetaminophen is an alternative to the NSAIDs. Although usually considered equivalent to aspirin as an analgesic and antipyretic agent, it lacks anti-inflammatory properties.

Opioid Analgesics. The term opioid or narcotic is used to refer to a group of medications, natural or synthetic, which has morphine-like actions. The older term opiate was used to designate drugs derived from opium—morphine, codeine, and many other semisynthetic congeners of morphine. Opioids are used for relief of short-term pain and for more long-term use in conditions such as cancer pain. When given for temporary relief of severe pain, such as that occurring after surgery, there is much evidence that opioids given routinely before the pain starts (preemptive analgesia) or becomes extreme are far more effective than those administered in a sporadic manner. People who are treated in this manner seem to require fewer doses and are able to resume regular activities sooner.

Although the analgesic and psychopharmacologic properties of morphine have been known for centuries, the fact that the brain contains its own endogenous opioid-like chemicals, the endorphins (enkephalins, endorphins, and dynorphins), has become known only within the last 40 to 50 years. The opioid analgesics are characterized by their interaction with three types of opioid receptors, designated μ (for “morphine”), δ, and κ. Each receptor type has been cloned, and subtypes have been identified using receptor-binding and molecular studies. Morphine and most opioids that are used clinically exert their effects through the μ receptor. Kappa receptor opioids are effective analgesics, but their side effects have proven troublesome, and the clinical impact of delta receptor opioids has been negligible.

It is well documented that the μ receptors modulate both the therapeutic effect of analgesia, as well as the side effects of respiratory depression, miosis, reduced gastrointestinal motility (causing constipation), feelings of well-being or euphoria, and physical dependence. The μ receptors are found at presynaptic and postsynaptic sites in the spinal dorsal horn and in the ascending pathways of the brain stem, thalamus, and cortex as well as the descending inhibitory system that modulates pain at the spinal cord. Their spinal location has been used clinically by direct application of opioid analgesics to the spinal cord by injection, infusion, or implantable intrathecal device (pump), which provides regional anesthesia while minimizing the unwanted respiratory depression, nausea and vomiting, and sedation that occur with systemically administered drugs that act at the brain level. Mu receptors are also found in peripheral sensory neurons after inflammation. This location supports the exploration and eventual clinical use of locally applied opioids (e.g., intra-articular instillation of opioids after knee surgery).

As more information becomes available regarding the opioids and their receptors, it seems likely that pain medications can be developed that act selectively at certain receptor sites, providing more effective pain control while producing fewer adverse effects and affording less danger of addiction.

Adjuvant Analgesics. Adjuvant analgesics include medications such as tricyclic antidepressants, antiseizure medications, and neuroleptic anxiolytic agents. The fact that the pain suppression system has nonendorphin synapses raises the possibility that potent, centrally acting, nonopiate medications may be useful in relieving pain. Serotonin has been shown to play an important role in producing analgesia. The tricyclic antidepressant medications (i.e., imipramine, amitriptyline, and doxepin) that block the removal of serotonin from the synaptic cleft have been shown to produce pain relief in some people. These medications are particularly useful in some chronic painful conditions, such as postherpetic neuralgia.
Certain antiseizure medications, such as carbamazepine and gabapentin, have analgesic effects in some pain conditions. These medications, which suppress spontaneous neuronal firing, are particularly useful in the management of pain that occurs after nerve injury (neuropathic pain), including diabetic neuropathy and chronic regional pain syndrome. Other agents, such as the corticosteroids, may be used to decrease inflammation and the nociceptive stimuli responsible for pain.17

**Surgical Intervention**

If surgery removes the problem causing the pain, such as a tumor pressing on a nerve or an inflamed appendix, it can be curative. In other instances, surgery is used for symptom management rather than for cure. Surgery for severe, intractable pain of peripheral or central origin has met with some success. It can be used to remove the cause or block the transmission of intractable pain from phantom limb pain, severe neuralgia, inoperable cancer of certain types, and causalgia.

**IN SUMMARY**

Pain is an elusive and complex phenomenon; it is a symptom common to many illnesses. It is a highly individualized experience that is shaped by a person’s culture and previous life experiences, and it is difficult to measure. Scientifically, pain is viewed within the context of nociception. Nociceptors are receptive nerve endings that respond to noxious stimuli. Pain receptors respond to mechanical, thermal, and chemical stimuli. Nociceptive neurons transmit impulses to the dorsal horn neurons using chemical neurotransmitters. The neospinothalamic and the paleospinothalamic pathways are used to transmit pain information to the brain. Several neuroanatomic pathways as well as endogenous opioid peptides modulate pain in the CNS.

Pain can be classified according to duration, location, and referral as well as associated medical diagnoses. Acute pain is self-limiting pain that ends when the injured tissue heals, whereas chronic pain is pain that lasts much longer than the anticipated healing time for the underlying cause of the pain. Pain can arise from cutaneous, deep somatic, or visceral locations. Referred pain is pain perceived at a site different from its origin. Pain threshold, pain tolerance, age, sex, and other factors affect a person’s reaction to pain.

Treatment modalities for pain include the use of physiologic, cognitive, and behavioral measures; heat and cold; stimulation-induced analgesic methods; and pharmacologic agents singly or in combination. It is becoming apparent that even with chronic pain, the most effective approach is early treatment or even prevention. After pain is present, the greatest success in pain assessment and management is achieved with the use of an interdisciplinary approach.

**ALTERATIONS IN PAIN SENSITIVITY AND SPECIAL TYPES OF PAIN**

After completing this chapter, you should be able to meet the following objectives:

- Define allodynia, hypoesthesia, hyperesthesia, paresthesias, hyperpathia, analgesia, and hypoalgesia and hyperalgesia.
- Describe the cause and characteristics and treatment of neuropathic pain, trigeminal neuralgia, postherpetic neuralgia, and complex regional pain syndrome.
- Discuss possible mechanisms of phantom limb pain.

**Alterations in Pain Sensitivity**

Sensitivity to and perception of pain vary among people and in the same person under different conditions and in different parts of the body. Irritation, mild hypoxia, and mild compression of a peripheral nerve often result in hyperexcitability of the sensory nerve fibers or cell bodies. This is experienced as unpleasant hypersensitivity (i.e., hyperesthesia) or increased painfulness (i.e., hyperalgesia). Primary hyperalgesia describes pain sensitivity that occurs directly in damaged tissues. Secondary hyperalgesia occurs in the surrounding uninjured tissue. Possible causes of hyperalgesia include increased sensitivity to noxious stimuli, a decrease in the threshold of nociceptors, an increase in pain produced by suprathreshold stimuli, and the windup phenomenon.19

Hyperpathia is a syndrome in which the sensory threshold is raised, but when it is reached, continued stimulation, especially if repetitive, results in a prolonged and unpleasant experience. This pain can be explosive and radiates through a peripheral nerve distribution. It is associated with pathologic changes in peripheral nerves, such as localized ischemia. Spontaneous, unpleasant sensations called paresthesias occur with more severe irritation (e.g., the pins-and-needles sensation that follows temporary compression of a peripheral nerve). The general term dysesthesia is given to distortions (usually unpleasant) of somesthetic sensation that typically accompany partial loss of sensory innervation.

More severe pathologic processes can result in reduced or lost tactile (e.g., hypoesthesia, anesthesia), temperature (e.g., hypothermia, athermia), and pain sensation (i.e., hypoalgesia). Analgesia is the absence of pain on noxious stimulation or the relief of pain without loss of consciousness. The inability to sense pain may result in trauma, infection, and even loss of a body part or parts. Inherited insensitivity to pain may take the form of congenital indifference or congenital insensitivity to pain. Congenital indifference is when the transmission of nerve impulses appears normal but appreciation of painful stimuli at higher levels appears to be absent. Congenital insensitivity is when a peripheral nerve defect apparently exists such that the transmission of painful nerve impulses does not
result in perception of pain. Whatever the cause, people who lack the ability to perceive pain are at constant risk of tissue damage because pain is not serving its protective function.20

Allodynia (Greek allo, “other,” and odynia, “painful”) is the term used for the puzzling phenomenon of pain that follows a nonnoxious stimulus to apparently normal skin. Nonnoxious stimuli may include wind, touching sheets, and showering. This term is intended to refer to instances in which otherwise normal tissues may be abnormally innervated or may be referral sites for other loci that give rise to pain with nonnoxious stimuli. It can result from increased responsiveness within the spinal cord (central sensitization) or a reduction in the threshold for nociceptor activation (peripheral sensitization). One type of allodynia involves trigger points, which are highly localized points on the skin or mucous membrane that can produce immediate intense pain at that site or elsewhere when stimulated by light tactile stimulation. Myofascial trigger points are foci of exquisite tenderness found in many muscles and can be responsible for pain projected to sites remote from the points of tenderness. Trigger points are widely distributed in the back of the head and neck and in the lumbar and thoracic regions. These trigger points cause reproducible myofascial pain syndromes in specific muscles. These pain syndromes are the major source of pain in people at chronic pain treatment centers.

Special Types of Pain

Neuropathic Pain

Neuropathic pain refers to pain that is caused by some problem with the neurological system. When peripheral nerves are affected by injury or disease, it can lead to unusual and sometimes intractable sensory disturbances. The notable features that point to neuropathic processes as a cause of pain include widespread pain that is not otherwise explainable and evidence of sensory deficit (e.g., numbness, paresthesias). Depending on the cause, few or many axons could be damaged and the condition could be unilateral or bilateral. Neuropathic pain is distinguished from other pain conditions where the pain stimulus begins in nonneuronal tissues.

Causes of neuropathic pain can be categorized according to the extent of peripheral nerve involvement. Conditions that can lead to pain by causing damage to peripheral nerves in a single area include nerve entrapment, nerve compression from a tumor mass, and various neuralgias (e.g., trigeminal, postherpetic, and posttraumatic). Conditions that can lead to pain by causing damage to peripheral nerves in a wide area include diabetes mellitus, long-term alcohol use, and hypothyroidism. Diabetes often causes a length-dependent neuropathy (meaning that the longest axons in a peripheral nerve are most vulnerable). Injury to a nerve also can lead to a multisymptom, multisystem syndrome called complex regional pain syndrome. Nerve damage associated with amputation is believed to be a cause of phantom limb pain.

Neuropathic pain can vary with the extent and location of disease or injury. There may be allosthenia or pain that is stabbing, jabbing, burning, or shooting. The pain may be persistent or intermittent. The diagnosis depends on the mode of onset, the distribution of abnormal sensations, the quality of the pain, and other relevant medical conditions (e.g., diabetes, hypothyroidism, alcohol use, rash, or trauma). Injury to peripheral nerves sometimes results in pain that persists beyond the time required for the tissues to heal. Peripheral pathologic processes (e.g., neural degeneration, neurona formation, and generation of abnormal spontaneous neural discharges from the injured sensory neuron) and neural plasticity (i.e., changes in CNS function) are the primary working hypotheses to explain persistent neuropathic pain.

Treatment methods include measures aimed at restoring or preventing further nerve damage (e.g., surgical resection of a tumor causing nerve compression, improving glycometric control for people with diabetes who have painful neuropathies), and interventions for the palliation of pain. Although many adjuvant analgesics are used for neuropathic pain, pain control often is difficult. The initial approach in seeking adequate pain control is to try these drugs in sequence and then in combination also with nonpharmacological interventions. The adjuvant analgesics can be divided into two general classes, including neuropathic and bone pain. Often the neuropathic category of pain is treated with tricyclic antidepressants, antiepileptics, local anesthetics, and alpha 2 adrenergic agonists. Most frequently bone pain is treated with glucocorticoids, bisphosphonates, osteoclast inhibitors, and skeletal muscle relaxants.

Poor pain control or unacceptable side effects may lead to a trial with other medications. If there has been a poor response to the adjuvant analgesics, opioids also can be used. However, concerns about side effects and the remote possibility of addiction must be considered. When opioids are used, the use of long-acting opioids with a plan for breakthrough pain is desirable because it addresses the typically continuous nature of neuropathic pain. Nonpharmacologic therapies also are used for neurogenic pain. Electrical stimulation of the peripheral nerve or spinal cord can be used for radiculopathies and neuralgias.

Neuralgia

Neuralgia is characterized by severe, brief, often repetitive attacks of lightning-like or throbbing pain. It occurs along the distribution of a spinal or cranial nerve and usually is precipitated by stimulation of the cutaneous region supplied by that nerve.

Trigeminal Neuralgia. Trigeminal neuralgia, or tic douleurex, is one of the most common and severe neuralgias. It is characterized by recurring, sudden onset of sharp, stabbing, pains without numbness in one or more nerve branches of cranial nerve five. Considerable controversy remains regarding the pathophysiology of trigeminal neuralgia. However, most agree it is caused by demyelination of axons in the ganglion, root, and nerve. Treatment of trigeminal neuralgia includes pharmacologic and surgical modalities. Other interventions include avoidance of precipitating factors (e.g., stimulation of trigger
Postherpetic Neuralgia. Herpes zoster (also called shingles) is caused by the same herpes virus (varicella–zoster virus) that causes chickenpox and is thought to represent a localized recurrent infection by the varicella–zoster virus that has remained latent in the dorsal root ganglia since the initial attack of chickenpox. Reactivation of viral replication is associated with a decline in cellular immunity. The probability of developing herpes zoster increases after the age of 60. Increased risk of herpes zoster occurs with impaired cellular immunity.

During the acute attack of herpes zoster, the reactivated virus travels from the affected sensory ganglia and peripheral nerve to the skin of the corresponding dermatomes, causing a unilateral localized vesicular eruption and hyperpathia. In the acute infection, proportionately more of the large nerve fibers are destroyed. Regenerated fibers appear to have smaller diameters. Because there is a relative loss of large fibers with age, older adults are particularly prone to suffering because of the shift in the proportion of large- to small-diameter nerve fibers.

People with postherpetic neuralgia may suffer from constant pain (“burning, aching, throbbing”), intermittent pain (“stabbing, shooting”), and stimulus-evoked pain (alldynia).

Early treatment of shingles with antiviral drugs such as acyclovir or valacyclovir that inhibit herpes virus deoxyribonucleic acid (DNA) replication may reduce the severity of herpes zoster. Initially, postherpetic neuralgia can be treated with a topical anesthetic agent, lidocaine–prilocaine cream or 5% lidocaine gel. A tricyclic antidepressant medication, such as amitriptyline or desipramine, may be used for pain relief. Regional nerve blockade has been used with limited success.

A recent trial investigating a new live attenuated herpes zoster vaccine among adults 60 years of age and older, designed to boost their cell-mediated immunity to the varicella–zoster virus, demonstrated dramatic decreases in the incidence of herpes zoster and postherpetic neuralgia. As a result, the vaccine, Zostavax, was approved by the U.S. Food and Drug Administration (FDA) for prevention of herpes zoster in persons 60 years of age and older and offers approximately 60% protection.

Phantom Limb Pain
Phantom limb pain, a type of neurologic pain, follows amputation of a limb or part of a limb. The pain can start out as tingling, squeezing, or heaviness, followed by burning, cramping, or shooting pain. It may disappear spontaneously or persist for many years. Evidence suggests that soldiers who had amputations in the field and had limited anesthetic were less apt to experience phantom pain than those who had comprehensive general anesthesia during their surgeries.

There are multiple theories as to the causes of phantom limb pain. One rationale is that the end of a regenerating nerve becomes trapped in the scar tissue of the amputation site. It is known that when a peripheral nerve is cut, the scar tissue that forms becomes a barrier to regenerating outgrowth of the axon. The growing axon often becomes trapped in the scar tissue, forming a tangled growth (i.e., neuroma) of small-diameter axons, including primary nociceptive afferents and sympathetic efferents. It has been proposed that these afferents show increased sensitivity to innocuous mechanical stimuli and to sympathetic activity and circulating catecholamines. A related theory moves the source of phantom limb pain to the spinal cord, suggesting that the pain is due to the spontaneous firing of spinal cord neurons that have lost their normal sensory input from the body. In this case, a closed self-exciting neuronal loop in the posterior horn of the spinal cord is postulated to send impulses to the brain, resulting in pain. Even the slightest irritation to the amputated limb area can initiate this cycle. Other theories propose that the phantom limb pain may arise in the brain itself. In one hypothesis, the pain is caused by changes in the flow of signals through somatosensory areas of the brain.

In other words, there appears to be plasticity even in the adult CNS. Treatment of phantom limb pain has been accomplished by the use of sympathetic blocks, TENS of the large myelinated afferents innervating the area, hypnosis, and relaxation training.

Pain may occur with or without an adequate stimulus, or it may be absent in the presence of an adequate stimulus—either of which describes a pain disorder. There may be analgesia (absence of pain), hyperalgesia (increased sensitivity to pain), hypoalgesia (a decreased sensitivity to painful stimuli), hyperpathia (an unpleasant and prolonged response to pain), hyperesthesia (an abnormal increase in sensitivity to sensation), hypesthesia (an abnormal decrease in sensitivity to sensations), paresthesia (abnormal touch sensation such as tingling or “pins and needles” in the absence of external stimuli), or allodynia (pain produced by stimuli that do not normally cause pain).

Neuropathic pain may be due to trauma or disease of neurons in a focal area or in a more global distribution (e.g., from endocrine disease or neurotoxic medications). Neuropathic pain is characterized by severe, brief, often repetitive attacks of lightning-like or throbbing pain that occurs along the distribution of a spinal or cranial nerve and usually is precipitated by stimulation of the cutaneous region supplied by that nerve. Trigeminal neuralgia, or tic douloureux, is one of the most common and severe neuralgias. It is manifested by facial tics or spasms. Postherpetic neuralgia is a chronic pain that can occur after shingles, an infection of the dorsal root ganglia and corresponding areas of innervation by the varicella–zoster virus. Phantom limb pain, a neurologic pain, can occur after amputation of a limb or part of a limb.
Headache

Headache is a very common health problem. Over 18 million Americans visit their health care provider because of a headache annually. Although head and facial pain have characteristics that distinguish them from other pain disorders, they also share many of the same features.

Headache is caused by a number of conditions. Some headaches represent primary disorders and others occur secondary to other disease conditions in which head pain is a symptom. The most common types of primary or chronic headaches are migraine headache, tension-type headache, cluster headache, and chronic daily headache (CDH). Although most causes of secondary headache are benign, some are indications of serious disorders such as meningitis, brain tumor, or cerebral aneurysm. Other times a person may experience a headache post head trauma. Generally the research suggests people with mild traumatic brain injury (TBI) have more headaches post head trauma than those with moderate or severe TBI. The sudden onset of a severe, intractable headache in an otherwise healthy person is more likely related to a serious intracranial disorder, such as subarachnoid hemorrhage or meningitis, than to a chronic headache disorder. Headaches that disturb sleep, exertional headaches (e.g., triggered by physical or sexual activity or a Valsalva maneuver), and headaches accompanied by neurologic symptoms such as drowsiness, visual or limb disturbances, or altered mental status also are suggestive of underlying intracranial lesions or other pathologic processes. Other red flags for secondary headache disorder include a fundamental change or progression in headache pattern or a new headache in people older than 50 years of age, or in people with cancer, immunosuppression, or pregnancy. Older adults need a comprehensive assessment of any headache if they have not had headaches before becoming an older adult.

The diagnosis and classification of headaches often is difficult. It requires a comprehensive history and physical examination to exclude secondary causes. The history should include factors that precipitate headache, such as foods and food additives, missed meals, and association with the menstrual period. A careful medication history is essential because many medications can provoke or aggravate headaches. Alcohol also can cause or aggravate headache. A headache diary in which the person records his or her headaches and concurrent or antecedent events may be helpful in identifying factors that contribute to headache onset.

In 2004, the International Headache Society (IHS) published the second edition of the International Classification of Headache Disorders (ICHD-2). The classification system is divided into three sections: (1) primary headaches, (2) headaches secondary to other medical conditions, and (3) cranial neuralgias and facial pain. Primary headaches, including migraine, cluster headache, tension-type headache, and other trigeminal autonomic cephalalgias, are discussed below. CHD and facial pain caused by TMJ pain are also discussed.

Migraine Headache

Migraine headaches affect a large number of people and especially women. Migraine headaches tend to run in families and are thought to be inherited as an autosomal dominant trait with incomplete penetrance.

Etiology and Pathogenesis

The pathophysiologic mechanisms of the pain associated with migraine headaches remain poorly understood. Although many alternative theories exist, it is well established that during a migraine the trigeminal nerve becomes activated. Stimulation of the trigeminal sensory fibers may lead to the release of neuropeptides, causing painful neurogenic inflammation within the meningeal vasculature. Another possible mechanism implicates neurogenic vasodilation of meningeal blood vessels as a key component of the inflammatory processes that occur during migraine. Supporting the neurogenic basis for migraine is the frequent presence of premonitory symptoms before the headache begins: the presence of focal neurologic disturbances, which cannot be explained in terms of cerebral blood flow. Hormonal variations, particularly in estrogen levels, play a role in the pattern of migraine attacks. For many women, migraine headaches coincide with their menstrual periods. Dietary substances, such as monosodium glutamate, aged cheese, and chocolate, also may precipitate migraine headaches. The actual triggers for migraine are the chemicals in the food, not allergens.

Clinical Manifestations

The ICHD-2 classifies migraine headaches into five major categories, the two most important of which are migraine without aura, which accounts for approximately 85% of migraines, and migraine with aura, which accounts for most of the remaining migraines.

Migraine without aura is a pulsatile, throbbing, unilateral headache that typically lasts 1 to 2 days and is aggravated by routine physical activity. The headache is accompanied by nausea and vomiting, which often is disabling, and sensitivity to light and sound. Visual disturbances occur quite commonly and
consist of visual hallucinations such as stars, sparks, and flashes of light. Migraine with aura has similar symptoms, but with the addition of reversible visual symptoms, including positive features (e.g., flickering lights, spots, or lines) or negative features (loss of vision); fully reversible sensory symptoms, including positive features (feeling of pins or needles) or negative features (numbness); and fully reversible speech disturbances or neurologic symptoms that precede the headache. The aura usually develops over a period of 5 to 20 minutes and lasts from 5 minutes to an hour. Although only a small percentage of people with migraine experience an aura before an attack, many people without aura have prodromal symptoms, such as fatigue and irritability, that precede the attack by hours or even days.

The other ICHD-2 migraine headache categories are retinal migraine, complications of migraine (e.g., chronic migraine, migrainous infarction, and migraine-triggered seizures), and childhood periodic syndromes that are commonly precursors of migraine. Retinal migraines are a rare form of migraine characterized by recurrent attacks of fully reversible scintillations (visual sensation of sparks or flashes of light), scotomata (visual blind spots), or blindness affecting one eye, followed within an hour by migrainous headache. The ICHD-2 classifies chronic migraine when a headache meeting the criteria for migraine is present on 15 or more days per month for 3 months or more, in the absence of medication overuse. Migrainous infarction is an uncommon occurrence in which one or more otherwise typical aura symptoms persist beyond 1 hour and neuroimaging confirms ischemic infarction. Strictly applied, these criteria distinguish this disorder from stroke, which must be excluded.

Migraine headache also can present as a mixed headache, including symptoms typically associated with tension-type headache, sinus headache, or CHD. These are called transformed migraine and are difficult to classify. Although nasal symptoms are not one of the diagnostic criteria for migraine, they frequently accompany migraine and are probably due to cranial parasympathetic activation. Sinus pain may indicate either a headache due to sinus inflammation or migraine.

Migraine headaches occur in children as well as adults. Before puberty, migraine headaches are equally distributed between the sexes. The essential diagnostic criterion for migraine in children is the presence of recurrent headaches separated by pain-free periods. Diagnosis is generally based on the child experiencing three of the following—abdominal pain, nausea or vomiting, throbbing headache, unilateral location, associated aura, relief during sleep, and a positive family history. Symptoms vary widely among children, from those that interrupt activities and cause the child to seek relief in a dark environment to those detectable only by direct questioning. A common feature of migraine in children is intense nausea and vomiting. The vomiting may be associated with abdominal pain and fever. Thus, migraine may be confused with other conditions such as appendicitis. Because headaches in children can be a symptom of other, more serious disorders, including intracranial lesions, it is important that other causes of headache be ruled out.

**Treatment**

The treatment of migraine headaches includes preventive and abortive nonpharmacologic and pharmacologic treatment.

Nonpharmacologic treatment includes the avoidance of migraine triggers, such as foods or smells that precipitate an attack. Many people with migraines benefit from maintaining regular eating and sleeping habits. Measures to control stress, which also can precipitate an attack, also are important. During an attack, many people find it helpful to retire to a quiet, darkened room until symptoms subside.

Pharmacologic treatment involves both abortive therapy for acute attacks and preventive therapy. A wide range of medications is used to treat the acute symptoms of migraine headache. Based on clinical trials, first-line agents include acetaminophen, acetalsalicylic acid, and caffeine; NSAIDs (e.g., naproxen sodium, ibuprofen); serotonin (5-HT) receptor agonists (e.g., sumatriptan, naratriptan, rizatRIPTAN, zolmitriptan); ergotamine derivatives (e.g., dihydroergotamine); and antiemetic medications (e.g., ondansetron, metoclopramide). Nonoral routes of administration may be preferred in people who develop severe pain rapidly or on awakening, or in those with severe nausea and vomiting. Sumatriptan has been approved for intranasal administration. Frequent use of abortive headache medications may cause rebound headache.

Preventive pharmacologic treatment may be necessary if migraine headaches become disabling, if they occur more than two or three times a month, if abortive treatment is being used more than two times a week, or if the person has hemiplegic migraine, migraine with prolonged aura, or migrainous infarction. In most cases, preventive treatment must be taken daily for months to years. First-line agents include β-adrenergic blocking medications (e.g., propranolol, atenolol), antidepressants (amitriptyline), and antiseizure medications (divalproex sodium, sodium valproate). When a decision to discontinue preventive therapy is made, the medications should be withdrawn gradually.

Other effective medications are available, but they can have serious side effects in some people. For example, because of the risk of coronary vasospasm, the 5-HT receptor agonists should not be given to people with coronary artery disease.

**Cluster Headache**

Cluster headaches are relatively uncommon headaches that occur more frequently in men than women and typically begin in the third decade of life. These headaches tend to occur in clusters over weeks or months, followed by a long, headache-free remission period. Cluster headache is a type of primary neurovascular headache that typically includes severe, unremitting, unilateral pain.

**Etiology and Pathogenesis**

The underlying pathophysiologic mechanisms of cluster headaches are not completely known, although recently it has been noted that heredity, through an autosomal dominant gene, plays some role in the pathogenesis of cluster headache.
The most likely pathophysiologic mechanisms include the interplay of vascular, neurogenic, metabolic, and humoral factors. Activation of the trigeminovascular system and the cranial autonomic parasympathetic reflexes is thought to explain the pain and autonomic symptoms. The hypothalamus is believed to play a key role. The possible role of the regulating centers in the anterior hypothalamus is implicated from observations of circadian biologic changes and neuroendocrine disturbances (e.g., changes in cortisol, prolactin, and testosterone) that occur in both active periods and during clinical remission. Magnetic resonance imaging has demonstrated dilated intracranial arteries on the painful side. Loss of vascular tone is believed to result from a defect in the sympathetic perivascular innervation.

Clinical Manifestations
The pain associated with cluster headache is of rapid onset and builds to a peak in approximately 10 to 15 minutes, lasting for 15 to 180 minutes. The pain behind the eye radiates to the ipsilateral trigeminal nerve (e.g., temple, cheek, gum). The headache frequently is associated with one or more symptoms such as restlessness or agitation, conjunctival redness, lacrimation specifically on one side, nasal congestion, rhinorrhea, forehead and facial sweating, miosis, ptosis, and eyelid edema.

Treatment
Because of the relatively short duration and self-limited nature of cluster headache, oral preparations typically take too long to reach therapeutic levels. The most effective treatments are those that act quickly. Oxygen inhalation may be indicated for home use. Prophylactic medications for cluster headaches include verapamil, lithium carbonate, corticosteroids, and sodium valproate.27

Tension-Type Headache
The most common type of headache is tension-type headache. Unlike migraine and cluster headaches, tension-type headache usually is not sufficiently severe that it interferes with daily activities.

Etiology and Pathogenesis
The exact mechanisms of tension-type headache are not known and the hypotheses of causation are contradictory. One popular theory is that tension-type headache results from sustained tension of the muscles of the scalp and neck; however, some research has found no correlation between muscle contraction and tension-type headache. It is thought that migraine headache may be transformed gradually into chronic tension-type headache. Tension-type headaches also may be caused by oromandibular dysfunction, psychogenic stress, anxiety, depression, and muscular stress. They also may result from overuse of analgesics or caffeine.

Clinical Manifestations
Tension-type headaches frequently are described as dull, ach- ing, diffuse, nondescript headaches, occurring in a hatband distribution around the head, and not associated with nausea or vomiting or worsened by activity. They can be infrequent, episodic, or chronic.

Treatment
Tension-type headaches often are more responsive to nonpharmacologic techniques, such as biofeedback, massage, acupuncture, relaxation, imagery, and physical therapy, than other types of headache. For people with poor posture, a combination of range-of-motion exercises, relaxation, and posture improvement may be helpful.

The medications of choice for acute treatment of tension-type headaches are analgesics, including acetysalicylic acid; acetaminophen; and NSAIDs.16,27 People with infrequent tension-type headache usually self-medicate using over-the-counter analgesics to treat the acute pain and do not require prophylactic medication. These agents should be used cautiously because rebound headaches can develop when the medications are taken regularly.

Because the “dividing lines” between tension-type headache, migraine, and CDH often are vague, addition of medications as well as the entire range of migraine medications may be tried in refractory cases. Other medications used concomitantly with analgesics include sedating antihistamines (e.g., promethazine and diphenhydramine), antiemetics (e.g., metoclopramide and prochlorperazine), or sedatives (e.g., butalbital).

Chronic Daily Headache
The term chronic daily headache is used to refer to headaches that occur 15 days or more a month, for greater than 3 months.27 Little is known about the prevalence and incidence of CDH. Diagnostic criteria for CDH are not provided in the IHS classification system.

Etiology and Pathogenesis
The cause of CDH is unknown, although there are several hypotheses. They include transformed migraine headache, evolved tension-type headache, new daily persistent headache, and posttraumatic headache. Although overuse of symptomatic medications has been related to CDH, there is a group of people in whom CDH is unrelated to excessive use of medications.

Clinical Manifestations
In many people, CDH retains certain characteristics of migraine, whereas in others it resembles chronic tension-type headache. CDH may be associated with chronic and episodic tension-type headache. New daily persistent headache may have a fairly rapidly onset, with no history of migraine, tension-type headache, trauma, or psychological stress.

Treatment
For people with CDH, a combination of pharmacologic and behavioral interventions may be necessary. As with tension-type headaches, nonpharmacologic techniques, such as biofeedback,
massage, acupuncture, relaxation, imagery, and physical therapy, may be helpful. Measures to reduce or eliminate medication, including caffeine, overuse may be helpful.

**Temporomandibular Joint Pain**

A common cause of head pain is temporomandibular joint (TMJ) syndrome. It usually is caused by an imbalance in joint movement because of poor bite, bruxism (i.e., teeth grinding), or joint problems.\(^2^6\) The pain almost always is referred and commonly presents as facial muscle pain, headache, neck ache, or earache. Referred pain is aggravated by jaw function. Headache associated with this syndrome is common in adults and children and can cause chronic pain problems.

Treatment of TMJ pain is aimed at correcting the problem, and in some cases this may be difficult. The initial therapy for TMJ should be directed toward relief of pain and improvement in function. Pain relief often can be achieved with use of the NSAIDs. Muscle relaxants may be used when muscle spasm is a problem.

**IN SUMMARY**

Head pain is a common disorder that is caused by a number of conditions. Some headaches represent primary disorders and others occur secondary to another disease state in which head pain is a symptom. Primary headache disorders include migraine headache, tension-type headache, cluster headache, and CDH. Although most causes of secondary headache are benign, some are indications of serious disorders such as meningitis, brain tumor, or cerebral aneurysm. TMJ syndrome is one of the major causes of headaches. It usually is caused by an imbalance in joint movement because of poor bite, teeth grinding, or joint problems such as inflammation, trauma, and degenerative changes.

**PAIN IN CHILDREN AND OLDER ADULTS**

After completing this chapter, you should be able to meet the following objectives:

- Differentiate between the pain response in children and older adults.
- Explain how pain assessment may differ in children and older adults.
- Explain how pain treatment may differ in children and older adults.

Pain frequently is underrecognized and undertreated in both children and older adults. In addition to the common obstacles to adequate pain management, such as concern about the effects of analgesia on respiratory status and the potential for addiction to opioids, there are additional deterrents to adequate pain management in children and older adults. In very young children and confused older adults, there are several additional factors. These include the extreme difficulty of assessing the location and intensity of pain in people who are cognitively immature or cognitively impaired and the argument that even if they feel pain, they do not remember it.\(^1^9\)

**Pain in Children**

Human responsiveness to painful stimuli begins in the neonatal period and continues through the life span. Although the specific and localized behavioral reactions are less marked in the younger neonate or the more cognitively impaired individual, protective or withdrawal reflexes in response to nociceptive stimuli are clearly demonstrated. Pain pathways, cortical and subcortical centers, and neurochemical responses associated with pain transmission are developed and functional by the last trimester of pregnancy. Neonates clearly perceive pain, as demonstrated by their integrated physiologic response to nociceptive stimuli. Dorsal horn neurons in neonates have a wider receptive field and lower excitatory threshold than those in older children.

As infants and children mature, their responses to pain become more complex and reflective of their maturing cognitive and developmental processes. Children do feel pain and have been shown to reliably and accurately report pain. They also remember pain. This is evidenced in studies of children with cancer, whose distress during painful procedures increases over time without intervention, and in neonates in intensive care units, who demonstrate protective withdrawal responses to a heel stick after repeated episodes.

**Pain Assessment**

To treat pain adequately, ongoing assessment of the presence of pain and response to treatment is essential.\(^1^8\) Self-report is usually regarded as the most reliable estimate of pain. With children 8 years of age or older, numeric scales (i.e., 1 to 10) and word graphic scales (i.e., “none,” “a little,” “most I have ever experienced”) can be used. With children 3 to 8 years of age, scales with faces of actual children or cartoon faces can be used to obtain a report of pain. Another supplementary strategy for assessing a child’s pain is to use a body outline and ask the child to indicate where the hurt is located. Particular care must be taken in assessing children’s reports of pain because their reports may be influenced by a variety of factors, including age, anxiety and fear levels, and parental presence. Some physiologic measures, such as heart rate, are convenient to measure and respond rapidly to brief nociceptive stimuli, but they are nonspecific. Relying on indicators of sympathetic nervous system activity and behaviors can also be problematic because they can be caused by things other than pain (e.g., anxiety and activity) and they do not always accompany pain, particularly chronic pain.

**Pain Management**

The management of children’s pain basically falls into two categories—pharmacologic and nonpharmacologic. In terms
of pharmacologic interventions, many of the analgesics used in adults can be used safely and effectively in children and adolescents. However, it is critical when using specific medications to determine that the medication has been approved for use with children and that it is dosed appropriately according to the child’s weight and level of physiologic development. Age-related differences in physiologic functioning, notably in neonates, will affect drug action. Neonates and infants have decreased levels of the hepatic enzymes needed for metabolism of many analgesics. The levels of these hepatic enzymes quickly increase to adult levels in the first few months of life. The renal excretion of drugs depends on renal blood flow, glomerular filtration rate, and tubular secretion, all of which are decreased in neonates, particularly premature neonates.

The overriding principle in all pediatric pain management is to treat each child’s pain on an individual basis and to match the analgesic agent with the cause and the level of pain. A second principle involves maintaining the balance between the level of side effects and pain relief such that pain relief is obtained with as little opioid and sedation as possible. One strategy toward this end is to time the administration of analgesia so that a steady blood level is achieved and, as much as possible, pain is prevented. This requires that the child receive analgesia on a regular dosing schedule, not “as needed.” Also, most drugs are packaged primarily for adult use, and dose calculations and serial dilutions may predispose to medication errors.

Nonpharmacologic strategies can be very effective in reducing the overall amount of pain and amount of analgesia used. In addition, some nonpharmacologic strategies can reduce anxiety and increase the child’s level of self-control during pain. Children can be taught to use simple distraction and relaxation and other techniques such as application of heat and cold. Other nonpharmacologic techniques can be taught to the child to provide psychological preparation for a painful procedure or surgery. These include positive self-talk, imagery, play therapy, modeling, and rehearsal. The nonpharmacologic interventions must be developmentally appropriate, and if possible, the child and parent should be taught these techniques when the child is not in pain (e.g., before surgery or a painful procedure) so that it is easier to practice the technique.

Pain in Older Adults

Among adults, the prevalence of pain in the general population increases with age. Research is inconsistent about whether there are age-related changes in pain perception. Some apparent age-related differences in pain may be due to differences in willingness to report the pain rather than actual differences in pain. The older adult may be reluctant to report pain so as not to be a burden or out of fear of the diagnoses, tests, medications, or costs that may result from an attempt to diagnose or treat their pain. It is important for the provider to ask very specific questions to older adults regarding their pain in order to elicit the correct information so best management of the pain can be given.

Pain Assessment

The assessment of pain in older adults can range from relatively simple in a well-informed, alert, cognitively intact person with pain from a single source and no comorbidities to extraordinarily difficult in a confused person. When possible, a person’s report of pain is the gold standard, but behavioral signs of pain should also be considered. Accurately diagnosing pain when the person has many health problems or some decline in cognitive function can be particularly challenging. In recent years, there has been increased awareness of the need to address issues of pain in people with dementia. The Assessment for Discomfort in Dementia Protocol is one example of the efforts to improve assessment and pain management in these people. It includes behavioral criteria for assessing pain and recommended interventions for pain. Its use has been shown to improve pain management.

Pain Management

When prescribing pharmacologic and nonpharmacologic methods of pain management for the older population, care must be taken to consider the cause of the pain, the person’s health status, the concurrent therapies, and the person’s mental status. In the older population, where the risk of adverse events is higher, the nonpharmacologic options are usually less costly and cause fewer side effects.

The role of mental focus and anxiety is important, and relaxation techniques, massage, and biofeedback may also be useful nonpharmacological interventions. Physical therapy and occupational therapy bring a variety of modalities, including the use of braces or splints, changes in biomechanics, and exercise, all of which have been shown to promote pain relief.

Although efficacy is important when considering the use of pharmacologic agents for pain relief in the elderly population, cost and safety must also be considered. Safety issues that must be considered among older adults include changes in drug metabolism, other disease comorbidity, and polypharmacy. Older adults may have physiologic changes that affect the pharmacokinetics of medications prescribed for pain management. These changes include decreased blood flow to organs, delayed gastric motility, reduced kidney function, and decreased albumin related to poor nutrition. Older adults also often have many coexisting health problems, leading to polypharmacy. The addition of analgesics to a complex medication regimen is even more likely to cause drug interactions and complicate compliance in older adults. However, these considerations should not preclude the appropriate use of analgesics to achieve pain relief. Nonopioids are generally the first line of therapy for mild to moderate pain, and acetaminophen is usually the first choice because it is relatively safe for older adults. Opioids are used for more severe pain and for palliative care. As with younger people, adjuvant analgesics are effectively used for treatment of pain in older adults. The use of some assessment tool to evaluate the level of pain and effectiveness of treatment is essential. Monitoring for side effects is also critical.
IN SUMMARY

Children experience and remember pain, and even fairly young children are able to accurately and reliably report their pain. Recognition of this has changed the clinical practice of health professionals involved in the assessment of children’s pain. Pharmacologic (including opioids) and nonpharmacologic pain management interventions have been shown to be effective in children. Nonpharmacologic techniques must be based on the developmental level of the child and should be taught to both children and parents.

Pain is a common symptom in older adults. Assessment, diagnosis, and treatment of pain in older adults can be complicated. Older adults may be reluctant or cognitively unable to report their pain. Diagnosis and treatment can be complicated by comorbidities and age-related changes in cognitive and physiologic function.

REVIEW EXERCISES

1. A 25-year-old man is admitted to the emergency department with acute abdominal pain that began in the epigastric area and has now shifted to the lower right quadrant of the abdomen. There is localized tenderness and guarding or spasm of the muscle over the area. His heart rate and blood pressure are elevated, and his skin is moist and cool from perspiring. He is given a tentative diagnosis of appendicitis and referred for surgical consultation.
   A. Describe the origin of the pain stimuli and the neural pathways involved in the pain that this man is experiencing.
   B. Explain the neural mechanisms involved in the spasm of the overlying abdominal muscles.
   C. What is the significance of his cool, moist skin and increased heart rate and blood pressure?

2. A 65-year-old woman with breast cancer is receiving hospice care in her home. She is currently receiving a long-acting opioid analgesic supplemented with a short-acting combination opioid and nonnarcotic medication for breakthrough pain.
   A. Explain the difference between the mechanisms and treatment of acute and chronic pain.
   B. Describe the action of opioid drugs in the treatment of pain.
   C. Define the terms tolerance and cross-tolerance as they refer to the use of opioids for treatment of pain.
   D. Describe the common side effects associated with the use of opioid drugs to relieve pain in persons with cancer.

3. A 42-year-old woman presents with sudden, stabbing-type facial pain that arises near the right side of her mouth and then shoots toward the right ear, eye, and nostril. She is holding her hand to protect her face because the pain is “triggered by touch, movement, and drafts.” Her initial diagnosis is trigeminal neuralgia.
   A. Explain the distribution and mechanisms of the pain, particularly the triggering of the pain by stimuli applied to the skin.
   B. What are possible treatment methods for this woman?

4. A 21-year-old woman presents to the student health center with complaints of a throbbing pain on the left side of her head, nausea and vomiting, and extreme sensitivity to light, noise, and head movement. She also tells you she had a similar headache 3 months ago that lasted for 2 days and states that she thinks she is developing migraines.
   A. Are this woman’s history and symptoms consistent with migraine headaches? Explain.
   B. Use the distribution of the trigeminal nerve and the concept of neurogenic inflammation to explain this woman’s symptoms.

5. A 72-year-old man presents to the emergency department after a fall with a complaint of the “worst headache ever experienced.” He is able to answer your questions with increasing difficulty.
   A. Differentiate primary headache from secondary headache.
   B. Given the information that you have, what type of headache do you suspect, and why?

Skeletal muscles are required to carry out skilled movements that coordinate and execute these contractions in a manner that provides for smooth, purposeful, and coordinated movement. In some cases, purposeless and disruptive movements can be almost as disabling as absence of movement. This chapter provides an introduction to the organization and control of motor function, followed by a discussion of disorders of motor function, including muscular dystrophy and disorders of the neuromuscular junction, peripheral nerves, basal ganglia and cerebellum, and upper motor neurons.
Chapter 19
Disorders of Motor Function

The Brain Stem

The brain stem contains two descending systems—the medial and lateral pathways (Fig. 19.2). The medial pathways provide for the basic postural control systems that the cortical motor areas use to organize highly differentiated movements. The medial pathways consist of tracts that descend in the ipsilateral ventral columns of the spinal cord and terminate in interneurons that influence motor neurons of axial and proximal muscles. These axial and proximal muscles are responsible for postural reflexes, such as those needed for pacing of steps during walking or running and recovery of posture when balance is disrupted.

The lateral brain stem pathways are more concerned with goal-directed movements. They terminate on the interneurons in the dorsolateral part of the spinal gray matter and thus influence the motor neurons that control distal muscles of the limbs. These descending pathways modify the activity of extensor and flexor motor neurons to produce complex motor movements such as walking and running.

The Motor Cortex

The cortex represents the highest level of motor function. The primary, premotor, and supplementary motor cortices located in the posterior part of the frontal lobe initiate and control precise, skillful, and intentional movements of the distal and especially flexor muscles of the limbs and speech apparatus.

These motor areas receive information from the thalamus and somatosensory cortex and, indirectly, from the cerebellum and basal ganglia.

The primary motor cortex (area 4 if using Brodmann classification of the brain cortical areas), also called the motor strip, is located on the rostral surface and adjacent portions of the central sulcus. The primary motor cortex controls specific muscle movement sequences. It is also the first level of descending control for precise motor movements. The neurons in the primary motor cortex are arranged in a somatotopic array or distorted map of the body called the motor homunculus (Fig. 19.4). The areas of the body that require the greatest dexterity have the largest cortical areas devoted to them. More than half of the primary motor cortex is concerned with controlling the muscles of the hands, of facial expression, and of speech.

The premotor cortex (Brodmann areas 6 and 8), which is located just anterior to the primary motor cortex, sends some fibers into the corticospinal tract but mainly innervates the primary motor strip. Nerve signals generated by the premotor cortex produce much more complex “patterns” of movement than the discrete patterns generated by the primary motor...
The Motor Unit

The motor neuron and the group of muscle fibers it innervates in a muscle are called a motor unit. When the motor neuron develops an action potential, all of the muscle fibers in the motor unit it innervates develop action potentials, causing them to contract simultaneously. Thus, a motor neuron and the muscle fibers it innervates function as a single unit—the basic unit of motor control.

Each motor neuron undergoes multiple branchings, making it possible for a single motor neuron to innervate a few to thousands of muscle fibers. In general, large muscles, those containing hundreds or thousands of muscle fibers and providing gross motor movement, have large motor units. This contrasts sharply with those that control the hand, tongue, and eye movements, for which the motor units are small and permit very precise control.

The motor neurons supplying a motor unit are located in the ventral horn of the spinal cord and are called lower motor neurons. UMNs, which exert control over LMNs, project from the motor strip in the cerebral cortex to the ventral horn and are fully contained in the central nervous system (CNS) (Fig. 19.5).

Spinal Reflexes

Reflexes are coordinated, involuntary motor responses that are initiated by a stimulus applied to peripheral receptors. Some reflexes, such as the flexor-withdrawal reflex, initiate
For skeletal muscle to perform normally, the brain must be continually informed of the current state of the muscles, and the muscles must exhibit tone (resistance to active and passive stretch at rest). This will depend on the transmission of information regarding the sense of body position, movement, and muscle tone to the CNS. Information from these sensory afferents is relayed to the cerebellum and cerebral cortex and is experienced as proprioception or the sense of body movement and position, independent of vision. The muscles and their tendons are supplied with two types of receptors to provide this information—muscle spindles and Golgi tendon organs. The muscle spindles, which are distributed throughout the belly of a muscle, relay information about muscle length and rate of stretch. The Golgi tendon organs are found in muscle tendons and transmit information about muscle tension or force of contraction at the junction of the muscle and the tendon that attaches to bone. Normal muscle tone depends on stretch reflexes initiated by the muscle spindles, which monitors changes in muscle length.

**FIGURE 19.5** • Motor pathways. Descending tracts carry motor and muscle information from the cortex to the cranial and peripheral nerves. (From Jensen S. (2011). *Nursing health assessment: A best practice approach* (p. 687). Philadelphia, PA: Lippincott Williams & Wilkins.)
The stretch reflex, a contraction of muscle fibers that occurs when a muscle is stretched, is essential to the control of muscle tone and maintenance of posture (see Understanding the Stretch Reflex and Muscle Tone). Stretch reflexes can be evoked in many muscles throughout the body and are tested routinely (e.g., knee-jerk reflex) during clinical examination for the diagnosis of neurologic conditions. Stretch reflexes tend to be hypoactive or absent in cases of peripheral nerve damage or ventral horn injury involving the test area. They are hyperactive when lesions of the corticospinal tract (e.g., stroke or spinal cord injury [SCI]) reduce or disrupt the inhibitory effect of the brain on the spinal cord.

The muscle spindles consist of a group of specialized miniature skeletal muscle fibers called **intrafusal fibers** that are encased in a connective tissue capsule and attached to the extrafusal fibers of a skeletal muscle. In the center of the receptor area, a large sensory neuron spirals around the intrafusal fiber, forming the so-called **primary or annulospiral ending**. The intrafusal muscle fibers function as stretch receptors. When a skeletal muscle is stretched, the spindle and its intrafusal fibers are stretched, resulting in increased firing of their afferent nerve fibers. Axons of these afferent neurons enter the spinal cord through several branches of the dorsal root. Some branches end in the segment of entry. Others ascend to adjacent segments, influencing intersegmental reflex function. Still others ascend in the dorsal column of the cord to the medulla of the brain stem. Segmental branches make connections, along with other branches, that pass directly to the anterior gray matter of the spinal cord and establish monosynaptic contact with each of the LMNs that have motor units in the muscle containing the spindle receptor. This produces an opposing muscle contraction. Another segmental branch of the same afferent neuron innervates an internuncial neuron that is inhibitory to motor units of antagonistic muscle groups. This disynaptic inhibitory pathway is the basis for the reciprocal activity of agonist and antagonist muscles (i.e., when an agonist muscle is stretched, the antagonists relax). Reciprocal innervation is useful not only for the stretch reflex but for voluntary movements. Relaxation of the antagonist muscle during movements enhances the speed and efficiency because the muscles that act as prime movers are not working against the contraction of opposing muscle.2

Another function of the stretch reflex is to inform the CNS of the status of muscle length. Ascending fibers from the stretch reflex ultimately provide information about muscle length to higher centers in the cerebellum and cerebral cortex. When a skeletal muscle lengthens or shortens against tension, a feedback mechanism needs to be available for readjustment such that the spindle apparatus remains sensitive to moment-to-moment changes in muscle stretch, even while changes in muscle length are occurring. This is accomplished by the gamma motor neurons that adjust spindle fiber length to match the length of the extrafusal muscle fiber. Descending fibers of motor pathways synapse with and simultaneously activate both alpha and gamma motor neurons so that the sensitivity of the spindle fibers is coordinated with muscle movement.

Central control over the gamma motor neurons also permits increases or decreases in muscle tone in anticipation of changes in the muscle force. The CNS, through its coordinated control of the muscle’s alpha and the spindle’s gamma motor neurons, can suppress the stretch reflex. This occurs during centrally programmed movements, such as pitching a baseball, that require a muscle to produce a full range of unopposed motion. Without this programmed adjustability of the stretch reflex, any movement is immediately opposed and prevented.

### Motor Pathways

The primary motor cortex contains many layers of pyramidal-shaped output neurons that

- Transmit to the premotor and somatosensory areas on same side of the cortex (i.e., premotor and somesthetic cortices)
- Transmit to the opposite side of the cortex
- Descend to subcortical structures such as the basal ganglia and thalamus

The large pyramidal cells located in the fifth layer transmit to the brain stem and spinal cord. The axons of these UMNs transmit through the subcortical white matter and internal capsule to the deep surface of the brain stem, through the ventral bulge of the pons, and to the ventral surface of the medulla, where they form a ridge or pyramid. About 90% of the corticospinal axons cross the midline at the junction of the medulla and cervical spinal cord to form the lateral corticospinal tract in the lateral white matter of the spinal cord.4 This tract extends throughout the spinal cord. The remaining 10% of uncrossed fibers travel down the ventral column of the cord, mainly to cervical levels, where they cross and innervate contralateral LMNs.4

Motor tracts are classified as belonging to one of two motor pathways—the pyramidal (direct) and extrapyramidal (indirect) pathways. According to this classification system, the pyramidal pathway consists of the motor pathways originating in the motor cortex and terminating in the corticobulbar fibers in the brain stem and the corticospinal fibers in the spinal cord. Other fibers from the cortex and basal ganglia project to the brain stem reticular formation and reticulospinal pathways to LMNs of proximal and extensor muscles. These fibers do not decussate in the pyramids, hence the name **extrapyramidal system**. Disorders of the pyramidal tracts (e.g., stroke) are characterized by spasticity and paralysis, whereas those affecting the extrapyramidal tracts (e.g., Parkinson disease) result in involuntary movements, muscle rigidity, and immobility without paralysis.

### Assessment of Motor Function

Assessing the motor system should include assessment of

- Body position
- Involuntary movements
- Muscle characteristics (strength, bulk, and tone)
- Spinal reflexes
- Coordination5
Muscle tone is controlled by the stretch reflex, which monitors changes in muscle length. The activity of the stretch reflex can be divided into three steps: (1) activation of the stretch receptors, (2) integration of the reflex in the spinal cord, and (3) regulation of reflex sensitivity by higher centers in the brain. Testing the knee-jerk reflex provides a means of assessing that reflex.

**Stretch Reflex Receptors**

Skeletal muscle is composed of two types of muscle fibers—a large number of extrafusal fibers, which control muscle movement, and a smaller number of intrafusal fibers, which control muscle tone. The intrafusal fibers are encapsulated in sheaths, forming a muscle spindle that runs parallel to the extrafusal fibers. Each intrafusal fiber is innervated by a large Ia sensory nerve fiber, which encircles the central noncontractile portion of the fiber to form the so-called annulospiral ending. Because the spindles are oriented parallel to the extrafusal muscle fibers, stretching of the extrafusal fibers also stretches the spindle fibers and stimulates the receptive endings of the Ia afferent neuron.

**Spinal Reflex Centers**

Afferent impulses from the Ia sensory fiber of the muscle spindle are transmitted to the spinal cord, where they synapse with alpha motor neurons of the stretched muscle to form a monosynaptic reflex arc—“monosynaptic” because only one synapse separates the primary sensory input from the motor neuron output. The reflex muscle contraction that follows resists further stretching of the muscle. As this spinal reflex activity is occurring, impulses providing information on muscle length are transmitted to higher centers in the brain. It is the coordinated activity of all the monosynaptic reflexes supplying the extrafusal fibers in a skeletal muscle that provides the muscle tone needed for organized movement.
Brain Center Connections

Although a spinal reflex can function independently, its sensitivity is adjusted by higher centers in the brain. Both types of muscle fibers are supplied with motor neurons—the extrafusal fibers with large alpha motor neurons, which produce muscle contraction, and the intrafusal fibers with smaller gamma motor neurons, which control the sensitivity of the stretch reflex. Descending fibers of motor pathways synapse with both alpha and gamma motor neurons, and the impulses are sent simultaneously to the large extrafusal fibers and to the intrafusal fibers to maintain muscle spindle tension (and sensitivity) during muscle contraction.

The Knee-Jerk Reflex

The knee-jerk reflex that occurs when the knee is tapped with a reflex hammer tests for the intactness of the stretch reflex arc in the quadriceps muscle. Stretching of the extrafusal fibers by tapping with a reflex hammer leads to lengthening of the intrafusal fibers and increased firing of the type Ia afferent neuron. Impulses from the Ia fiber enter the dorsal horn of the spinal cord and make monosynaptic contact with the ventral horn alpha motor neuron supplying the extrafusal fibers in the quadriceps muscle. The resultant reflex contraction (shortening) of the quadriceps muscle is responsible for the knee jerk. These muscle reflexes are called deep tendon reflexes. They can be checked at the wrists, elbows, knees, and ankles as a means of assessing the components of the stretch reflex at different spinal cord segments.
**Body Position and Involuntary Movements**

Observe the body position of the person when moving and at rest. Continually observe for involuntary movements, and note the location, quality, rate, and rhythm of the movements.

**Muscle Characteristics**

**Muscle Tone.** Muscle tone is the normal state of muscle tension. Palpate for muscle tone by palpating the muscle while at rest and during passive stretching. With the person at rest, the joints are put through the normal range of motion (flexion and extension) by the examiner. Disorders of skeletal muscle tone are characteristic of many nervous system lesions. Any interruption of the stretch reflex pathway by peripheral nerve injury, pathologic process of the neuromuscular junction, injury to the spinal cord, or damage to the corticospinal system can result in disturbances of muscle tone.

Abnormalities of muscle tone may be described as hypotonia (less than normal), flaccidity (absent), or hypertonia, rigidity, spasticity, or tetany (all indicating higher-than-normal tone). Typically, UMN lesions produce increased tone, whereas LMN lesions produce decreased tone. Increased resistance that varies and commonly becomes worse at the extremes of the range of motion is called spasticity. Resistance that becomes worse throughout the range and in both directions is called lead-pipe rigidity. Decreased resistance suggests disease of the LMNs or the acute stages of SCI. Marked flappiness indicates hypotonic or flaccid muscles.

**Spinal Reflex Activity**

Testing of deep tendon reflexes (DTRs) (see Understanding the Stretch Reflex and Muscle Tone) can provide important information about the status of the CNS in controlling muscle function. Hyperactive reflexes are suggestive of a UMN disorder. Clonus is the rhythmic contraction and alternate relaxation of a limb that is caused by suddenly stretching a muscle and gently maintaining it in the stretched position. It is seen in the hypertonia of spasticity associated with UMN lesions, such as SCI. Hyporeflexia or areflexia suggests the presence of an LMN lesion. The distribution of abnormality in the reflexes is also helpful in determining the location of the lesion. For example, hyperreflexia in both lower extremities would suggest a lesion in the spinal cord, whereas hyperreflexia on one side of the body would suggest a lesion in the UMN along the motor pathway (e.g., in the motor cortex or internal capsule).

**Coordination of Movement**

Coordination of muscle movement requires that four areas of the nervous system function in an integrated manner:

- The motor system for muscle strength
- The cerebellar system for rhythmic movement and steady posture
- The vestibular system for posture and balance
- The sensory system for position sense

In cerebellar disease, one movement cannot be followed quickly by its opposite movement, and movements are slow, irregular, clumsy, unsteady, and inappropriately varying in their speed, force, and direction. Dysdiadochokinesia is the failure to accurately perform rapid alternating movements. Ataxia is a term used to describe a wide-based, unsteady gait. Dysmetria is a term used to describe inaccuracies of movements leading to a failure to reach a specified target. It is possible to test for dysmetria by having the person touch the examiner’s finger and then alternately touch his or her finger. These movements are normally smooth and accurate. Asking the person to touch the examiner’s finger with an outstretched arm and finger, first with the eyes open and then closed, provides a test for position sense. Repetitive and consistent
deviation to one side (referred to as past pointing), which is worse with the eyes closed, suggests cerebellar or vestibular disease.

Chorea (abnormal writhing movements), dystonia (abnormal simultaneous contractions of agonist and antagonist muscles, leading to abnormal postures), tremor (rhythmic movements of a particular body part), bradykinesia (slowness of movements), and myoclonus (involuntary jerking movement) indicate abnormalities in the basal ganglia, although the exact localization may be difficult to determine.

**IN SUMMARY**

Motor function, whether it involves walking, running, or precise finger movements, requires movement and maintenance of posture. The system consists of the LMNs, which are located in the ventral horn of the spinal cord and the group of muscle fibers it innervates in the muscle; spinal cord circuitry and reflexes; and the UMN that project from the motor cortex to the opposite side of the medulla, where they form a pyramid before crossing the midline to form the lateral corticospinal tract in the spinal cord. The primary, premotor, and supplementary motor cortices provide the voluntary control of motor function which is directed by the motor cortex. The primary motor cortex is responsible for execution of a movement, the premotor cortex for generating a plan of movement, and the supplemental motor cortex for rehearsing the motor sequences of a movement, including those involving both sides of the body. As with other parts of the nervous system, the motor systems are organized in a functional hierarchy of, from bottom to top, the spinal cord, brain stem, and motor cortex, each with circuits that, through their input and output connections, can contribute to the organization and regulation of complex motor responses.

Proper control of muscle function requires the function of reflex circuitry that monitors the functional status of the muscle fibers on a moment-by-moment basis along with the excitation of the muscle by the LMNs located in the spinal cord. The muscle spindles of the stretch reflex function to monitor and correct for changes in muscle length when extrafusal fibers are either shortened (by contraction) or lengthened (by stretch).

Assessments of muscle strength and muscle bulk, muscle tone and motor reflexes, and patterns of motor movement and posture provide the means for determining the location of disorders of motor function. Paresis (weakness) and paralysis (loss of muscle movement) reflect a loss of muscle strength. UMN lesions tend to produce spastic paralysis and LMN lesions, flaccid paralysis. Changes in muscle bulk are characterized by a loss of muscle mass (atrophy) or an increase in muscle mass (hypertrophy). Muscle tone is maintained through the combined function of the spinal cord stretch reflex, and higher centers monitor and buffer UMN innervation of the LMNs. Hypotonia is a condition of less-than-normal muscle tone, and hypertonia or spasticity is a condition of excessive tone. Abnormal and uncoordinated movements and postures are suggestive of a cerebellar or basal ganglia pathologic process.

**Skeletal Muscle Disorders**

**Muscle Atrophy**

Maintenance of muscle strength requires relatively frequent movements against resistance. Reduced use results in muscle atrophy, which is characterized by a reduction in the diameter of the muscle fibers because of a loss of protein filaments.7 When a normally innervated muscle is not used for long periods, the muscle cells shrink in diameter, and although the muscle cells do not die, they lose much of their contractile proteins and become weakened. This is called disuse atrophy, and it occurs with conditions such as immobilization and chronic illness. Evidence suggests that all skeletal muscle atrophy is not exactly the same due to different signaling pathways that manage skeletal muscle protein turnover. If this is proven, individualized therapies can be developed for each type of disuse atrophy to allow more targeted prevention.8

The most extreme examples of muscle atrophy are found in people with disorders that deprive muscles of their innervation. This is called denervation atrophy. During early embryonic development, outgrowing skeletal nerves innervate partially mature muscle cells. If the developing muscle cells are not innervated, they do not mature and eventually die. In the process of innervation, randomly contracting muscle cells become enslaved by the innervating neurons, and from then on, the muscle cell contracts only when stimulated by that particular neuron.
If the LMN dies or its axon is destroyed, the skeletal muscle cell is again free of neural domination. When this happens, it begins to have temporary spontaneous contractions, called *fibrillations*. In contrast to previously described fasciculations, fibrillations are not visible clinically and can be detected only by electromyography (EMG). The muscle also begins to lose its contractile proteins, and, after several months, if not reinnervated, it is replaced by fibrous connective tissue, which makes rehabilitation difficult. Atrophy of denervation can often be delayed by electrically stimulating the muscle periodically while waiting to determine if the damaged nerve fiber regenerates.

**Muscular Dystrophy**

*Muscular dystrophy* is a term applied to a number of genetic disorders that produce progressive deterioration of skeletal muscles because of mixed muscle cell hypertrophy, atrophy, and necrosis. They are primary diseases of muscle tissue and probably do not involve the nervous system. As the muscle undergoes necrosis, fat and connective tissue replace the muscle fibers, which increases muscle size and results in muscle weakness (Fig. 19.6). The increase in muscle size resulting from connective tissue infiltration is called *pseudohypertrophy*. The muscle weakness is insidious in onset but continually progressive, varying with the type of disorder.

The most common form of the disease is DMD, which occurs once in every 3500 live male births. DMD is inherited as a recessive single-gene defect on the X chromosome and is transmitted from the mother to her male offspring. A spontaneous (mutation) form may occur in girls. Another form of dystrophy, *Becker muscular dystrophy*, is similarly X-linked but manifests later in childhood or adolescence and has a slower course of progression.

**Etiology and Pathogenesis.** DMD is caused by mutations in a gene located on the short arm of the X chromosome that codes for a protein called *dystrophin*. Dystrophin is a large cytoplasmic protein located on the inner surface of the sarcolemma or muscle fiber membrane. The dystrophin molecules are concentrated over the Z bands of the muscle, where they form a strong link between the actin filaments of the intracellular contractile apparatus and the extracellular connective tissue matrix. It is thought that abnormalities in the dystrophin-associated protein complex compromise sarcolemma integrity, particularly with sustained contractions. This disruption in integrity may be responsible for the observed increased fragility of dystrophic muscle, excessive influx of calcium ions, and release of soluble muscle enzymes such as creatine kinase into the serum. The degenerative process in DMD consists of a relentless necrosis of muscle fibers, accompanied by a continuous process of repair and regeneration, and progressive fibrosis. The degenerative process eventually outpaces the regenerative capacity of the muscle, causing a gradual replacement of muscle fibers by fibrofatty connective tissue. The end stage is characterized by almost complete loss of skeletal muscle fibers, with relative sparing of intrafusal fibers of the muscle spindles.

**Clinical Manifestations.** Signs of muscle weakness manifested by frequent falling usually become evident beginning when the child is between 2 and 3 years old. The postural
Treatment. Management of the disease is directed toward maintaining ambulation and preventing deformities. Passive stretching, correct or counter posturing, and splints help to prevent deformities. Precautions should be taken to avoid respiratory infections. Although there have been exciting advances in identifying the gene and gene product involved in DMD, there is no known cure. Research illustrates that people with severe versus mild DMD were determined to have much variability in their symptom onset and response to steroids during exacerbations. Due to the various possible genotypes of DMD, researchers recommend more focused management for people with DMD, depending on their specific genotype.10

Disorders of the Neuromuscular Junction

The neuromuscular junction serves as a synapse between a motor neuron and a skeletal muscle fiber. It consists of the axon terminals of a motor neuron and a specialized region of the muscle membrane called the motor end plate. The transmission of impulses at the neuromuscular junction is mediated by the release of the neurotransmitter acetylcholine from the axon terminals. Acetylcholine binds to specific receptors in the end-plate region of the muscle fiber surface to cause muscle contraction (Fig. 19.7). Acetylcholine is active in the neuromuscular junction only for the brief period of time that it takes to generate an action potential in the innervated muscle cell. In the synaptic space are large quantities of the enzyme acetylcholinesterase, which destroy acetylcholine a few milliseconds after it has been released. The rapid inactivation of acetylcholine allows repeated muscle contractions and gradations of contractile force.

Drug- and Toxin-Induced Disorders

A number of drugs can alter neuromuscular function by changing the release, inactivation, or receptor binding of acetylcholine. A drug that acts on the postjunctional membrane of the motor end plate to prevent the depolarizing effect of the

**FIGURE 19.7** • Neuromuscular junction. (A) Acetylcholine (ACh) released from the motor neurons in the myoneural junction crosses the synaptic space to reach receptors that are concentrated in the folds of the end plate of the muscle fiber. Once released, ACh is rapidly broken down by the enzyme acetylcholinesterase (ACh esterase). (B) Decrease in ACh receptors in myasthenia gravis.
neuromusculature is curare. To facilitate relaxation of involved musculature during surgical procedures, curare-type drugs are used to block the neuromuscular transmission. Drugs such as physostigmine and neostigmine inhibit the action of acetylcholinesterase and allow acetylcholine released from the motor neuron to accumulate and prolong its action. These drugs are used in the treatment of myasthenia gravis.

Myasthenia gravis is a disorder of transmission at the neuromuscular junction due to antibody-mediated attack on nicotinic AChR or muscle-specific tyrosine kinase (MuSK) that affects communication between the motor neuron and the innervated muscle. This autoimmune disease may occur at any age, but the peak incidence occurs in young adulthood. The disease is approximately three times more common in women than men. A smaller, second peak occurs in later life and affects men more often than women. The Lambert-Eaton myasthenic syndrome is an autoimmune disease of peripheral cholinergic synapses that occurs with small cell carcinoma of the lung. Neonatal myasthenia gravis, caused by placental transfer of the acetylcholine receptor antibody, occurs in about 10% of infants born to mothers with the disease. Spontaneous resolution of symptoms usually occurs within a few months of birth.

Etiology and Pathogenesis. As an autoimmune disease, the disorder is caused by an antibody-mediated loss of acetylcholine receptors in the neuromuscular junction (Fig. 19.7B). Although the exact mechanism that triggers the autoimmune response is unclear, it is thought to be caused by sensitized helper T cells and an antibody-directed attack on the acetylcholine receptor in the neuromuscular junction. The antibody attack leads to a shedding of the acetylcholine receptor–rich terminal portions of the folds in the end plate of the muscle fiber, a decreased number of receptors, and a widened synaptic space that impairs signal transmission. The antibodies do not directly block binding of acetylcholine to receptors in the neuromuscular junction 9

Clinical Manifestations. In people with myasthenia gravis who have a reduced postsynaptic membrane area and fewer acetylcholine receptors, each release of acetylcholine from the presynaptic membrane results in a lower-amplitude end-plate potential. This results in both muscle weakness and fatigability with sustained effort. Most commonly affected are the eye and periorbital muscles, with ptosis due to eyelid weakness or diplopia due to weakness of the extraocular muscles as an initial symptom. The disease may progress from ocular muscle weakness to generalized weakness, including respiratory muscle weakness. Chewing and swallowing may be difficult. Weakness in limb movement usually is more
pronounced in proximal than in distal parts of the extremity, so that climbing stairs and lifting objects are difficult. As the disease progresses, the muscles of the lower face are affected, causing speech impairment. In most people, symptoms are least evident when arising in the morning, but grow worse with effort and as the day proceeds.

People with myasthenia gravis may experience a sudden exacerbation of symptoms and weakness known as myasthenic crisis. Myasthenic crisis occurs when muscle weakness becomes severe enough to compromise ventilation to the extent that ventilatory support and airway protection are needed. Myasthenic crisis usually occurs during a period of stress, such as infection, emotional upset, pregnancy, alcohol ingestion, cold exposure, or surgery. Cholinergic crisis results from inadequate or excessive doses of the anticholinesterase drugs used in treatment of myasthenia gravis.

**Diagnosis and Treatment.** The diagnosis of myasthenia gravis is based on history and physical examination, the anticholinesterase test, nerve stimulation studies, and an assay for acetylcholine receptor antibodies. The anticholinesterase test uses an injection of neostigmine bromide (Prostigmin) or edrophonium (Tensilon) that inhibits acetylcholinesterase, the enzyme that decreases the breakdown of acetylcholine in the neuromuscular junction. When weakness is caused by myasthenia gravis, a dramatic transitory improvement in muscle function occurs. An advance in diagnostic methods for myasthenia gravis is single-fiber EMG, which is available in many medical centers. Single-fiber EMG detects delayed or failed neuromuscular transmission in muscle fibers supplied by a single nerve fiber. The standard EMG and nerve conduction velocities are usually normal. An immunoassay test can be used to detect the presence of antiacetylcholine receptor antibodies circulating in the blood. Research has found that Epstein-Barr virus, a lymphotropic human herpes virus, is present in the thymuses of many people with myasthenia gravis. Most children diagnosed with myasthenia gravis are found to already have antibodies to acetylcholine receptors, and their degree of disease is influenced by their genetics and environment.

Treatment methods include the use of pharmacologic agents; immunosuppressive therapy, including corticosteroid drugs; management of myasthenic crisis; thymectomy; and plasmapheresis or intravenous immunoglobulin. Medications that may exacerbate myasthenia gravis, such as the amino-glycoside antibiotics, should be avoided. Pharmacologic treatment with reversible anticholinesterase drugs inhibits the breakdown of acetylcholine at the neuromuscular junction by acetylcholinesterase. Pyridostigmine and neostigmine are the drugs of choice. Corticosteroid drugs, which suppress the immune response, are used in cases of a poor response to anticholinesterase drugs and thymectomy. Immunosuppressant drugs (e.g., azathioprine, cyclosporine) also may be used, often in combination with plasmapheresis.

Plasmapheresis removes antibodies from the circulation and provides short-term clinical improvement. It is used primarily to stabilize the condition of people in myasthenic crisis or for short-term treatment in people undergoing thymectomy. Intravenous immunoglobulin also produces improvement in people with myasthenia gravis. Although the effect is temporary, it may last for weeks to months. The indications for its use are similar to those for plasmapheresis. The mechanism of action of intravenous immunoglobulin is unknown. Thymectomy, or surgical removal of the thymus, may be used as a treatment for myasthenia gravis. Because the mechanism whereby surgery exerts its effect is unknown, the treatment is controversial. Removal of the thymus is frequently recommended for young people with myasthenia gravis, and these people generally have less of a progression of myasthenia.

**Lower Motor Neuron Disorders**

LMN diseases are progressive neurologic illnesses that selectively affect the anterior horn cells of the spinal cord and cranial nerve motor neurons. An example of a disorder that involves purely LMNs is a distinctive group of degenerative disorders that begin in childhood or adolescence called *spinal muscular atrophy* (SMA). Weakness and muscle atrophy are prominent findings in all forms of the disorder. This condition is likely to be inherited, usually in an autosomal recessive fashion, and is caused by the deletion of the survival motor neuron-1 gene (*SMN1*). This disorder is classified as type I (Werdnig-Hoffman disease), type II (intermediate), and type III (Kugelberg-Welander disease). Some forms of SMA result from degeneration of the anterior horn cells but are not caused by deletion of the *SMN1* gene. The most severe form may be symptomatic at birth or in the first months of life. In addition to hypotonia in the infant, people frequently die from respiratory failure.

**Peripheral Nerve Disorders**

The peripheral nervous system consists of the motor and sensory branches of the cranial and spinal nerves, the peripheral parts of the autonomic nervous system, and the peripheral ganglia. A peripheral neuropathy is any primary disorder of the peripheral nerves. The result usually is muscle weakness, with or without atrophy and sensory changes.

Unlike nerves in the CNS, peripheral nerves are fairly strong and resilient. They contain a series of connective tissue sheaths that enclose their nerve fibers. An outer fibrous sheath called the *epineurium* surrounds the medium-sized to large nerves. Inside, a sheath called the *perineurium* invests each bundle of nerve fibers. In addition, within each bundle, a delicate sheath of connective tissue known as the *endoneurium* surrounds each nerve fiber. Inside the endoneurial sheath are the Schwann cells that produce the myelin sheath that surrounds the peripheral nerves. Each Schwann cell can myelinate only one segment of a single axon—the one that it covers. Therefore, myelination of an entire axon requires the participation of a long line of these cells.
Peripheral Nerve Injury and Repair

There are two main types of peripheral nerve injury based on the target of the insult—segmental demyelination involving the Schwann cell and axonal degeneration involving the neuronal cell body or its axon. The peripheral nerve disorders can affect a spinal nerve or nerve root, a nerve plexus, peripheral nerve trunk (mononeuropathies), or multiple peripheral nerves (polyneuropathies).

**Segmental Demyelination.** Segmental demyelination occurs when there is a disorder of the Schwann cell (as in Guillain-Barré syndrome) or damage to the myelin sheath (e.g., sensory neuropathies), without a primary abnormality of the axon. It typically affects some Schwann cells while sparing others. The denuded axon provides a stimulus for remyelination, and the population of cells in the endoneurium has the capacity to replace the injured Schwann cells. These cells proliferate and encircle the axon and, in time, remyelinate the denuded portion. However, the new myelin sheath is thin in proportion to the axon, and over time, many chronic demyelinating neuropathies give way to axonal injury.

**Axonal Degeneration.** Axonal degeneration is caused by primary injury to a neuronal cell body or its axon. Damage to the axon may be due either to a focal event occurring at some point along the length of the nerve (e.g., trauma or ischemia) or to a more generalized abnormality affecting the neuronal cell body (neuropathy).

Damage to a peripheral nerve axon, whether due to injury or neuropathy, results in degenerative changes, followed by breakdown of the myelin sheath and Schwann cells. In distal axonal degeneration, the proximal axon and neuronal cell body, which synthesizes the material required for nourishing and maintaining the axon, remain intact. In neuropathies and crushing injuries in which the endoneurial tube remains intact, the outgrowing fiber will grow down this tube to the structure that was originally innervated by the neuron (Fig. 19.8). However, it can take weeks or months for the regrowing fiber to reach its target organ and for communicative function to be reestablished. More time is required for the Schwann cells to form new myelin segments and for the axon to recover its original diameter and conduction velocity.

The successful regeneration of a nerve fiber in the peripheral nervous system depends on many factors. If a nerve fiber is destroyed relatively close to the neuronal cell body, the chances are that the nerve cell will die, and if it does, it will not be replaced. If a crushing type of injury has occurred, partial or often full recovery of function occurs. Cutting-type trauma to a nerve is an entirely different matter. Connective scar tissue forms rapidly at the wound site, and when it does, only the most rapidly regenerating axonal branches are able to get through to the intact distal endoneurial tubes. A number of scar-inhibiting agents have been used in an effort to reduce this hazard, but have met with only moderate success. In another attempt to improve nerve regeneration, various types of tubular implants have been placed to fill longer gaps in the endoneurial tube.

**FIGURE 19.8** Sequential stages in efferent axon degeneration and regeneration within its endoneurial tube, after peripheral nerve crush injury. (PNS, peripheral nervous system.)

Neuropathies involving the neuronal cell body are much less common than those affecting the axons. In these cases, there is little potential for recovery of function because death of the neuronal cells precludes axonal regeneration.

**Mononeuropathies**

Mononeuropathies usually are caused by localized conditions such as trauma, compression, or infection that affect a single spinal nerve, plexus, or peripheral nerve trunk. Fractured bones may lacerate or compress nerves. Excessively tight tourniquets may injure nerves directly or produce ischemic injury. In addition, infections such as herpes zoster may affect a single segmental afferent nerve distribution. Recovery of nerve function usually is complete after compression lesions and incomplete or faulty after nerve transection.

**Carpal Tunnel Syndrome.** Carpal tunnel syndrome is a relatively common compression-type mononeuropathy. It is caused by compression of the median nerve as it travels with the flexor tendons through a canal made by the carpal
bones and transverse carpal ligament. The condition can be caused by a variety of conditions that produce a reduction in the capacity of the carpal tunnel (i.e., bony or ligamentous changes) or an increase in the volume of the tunnel contents (i.e., inflammation of the tendons, synovial swelling, or tumors). Most cases of carpal tunnel syndrome are due to repetitive use of the wrist (i.e., flexion–extension movements and stress associated with pinching and gripping motions).

Clinical Manifestations. Carpal tunnel syndrome is characterized by pain, paresthesia, and numbness of the thumb and first two and one half digits of the hand; pain in the wrist and hand, which worsens at night; atrophy of the abductor pollicis muscle; and weakness in precision grip. All of these abnormalities may contribute to clumsiness of fine motor activity.

Diagnosis and Treatment. Diagnosis usually is based on sensory disturbances confined to median nerve distribution and a positive Tinel or Phalen sign.16 The Tinel sign is the development of a tingling sensation radiating into the palm of the hand that is elicited by light percussion over the median nerve at the wrist. The Phalen maneuver is performed by having the person hold the wrist in complete flexion for approximately a minute. If numbness and paresthesia along the median nerve are reproduced or exaggerated, the test result is considered to be positive. EMG and nerve conduction studies often are done to confirm the diagnosis and exclude other causes of the disorder.

Treatment includes avoidance of movements that cause nerve compression, splinting, and anti-inflammatory medications. Measures to decrease the causative repetitive movements should be initiated. Splints may be confined to nighttime use. When splinting is ineffective, corticosteroids may be injected into the carpal tunnel to reduce inflammation and swelling. Surgical intervention consists of operative division of the volar carpal ligaments as a means of relieving pressure on the median nerve.

Polynuropathies

Polynuropathies involve demyelination or axonal degeneration of multiple peripheral nerves that leads to symmetric sensory, motor, or mixed sensorimotor deficits. Typically, the longest axons are involved first, with symptoms beginning in the distal part of the extremities. If the autonomic nervous system is involved, there may be postural hypotension, constipation, and impotence. Polynuropathies can result from immune mechanisms (e.g., Guillain-Barré syndrome), toxic agents (e.g., arsenic polynuropathy, lead polynuropathy, alcoholic polynuropathy), and metabolic diseases (e.g., diabetes mellitus, uremia). Different causes tend to affect axons of different diameters and to affect sensory, motor, or autonomic neurons to different degrees.

Guillain-Barré Syndrome. Guillain-Barré syndrome is an acute immune-mediated polynuropathy.17 The syndrome defines a clinical entity that is characterized by rapidly progressive ascending symmetrical limb weakness and loss of tendon reflexes. It has been described as the most common cause of acute, flaccid nontraumatic paralysis. There are several manifestations of the disorder, including pure motor axonal degeneration and axonal degeneration of both motor and sensory nerves.16 The disorder is manifested by infiltration of mononuclear cells around the capillaries of the peripheral neurons, edema of the endoneurial compartment, and demyelination of ventral spinal roots. The cause of the Guillain-Barré syndrome probably has an immune component. The majority of people report having had an acute, influenza-like illness before the onset of symptoms. In addition, about one third of people with Guillain-Barré syndrome have antibodies against nerve gangliosides.

Clinical Manifestations. Progressive ascending muscle weakness of the limbs, producing a symmetric flaccid paralysis, characterizes the disorder. Symptoms of paresthesia and numbness often accompany the loss of motor function. The rate of disease progression varies, and there may be disproportionate involvement of the upper or lower extremities.16 Paralysis may progress to involve the respiratory muscles, which will mandate the use of a ventilator for these people. Autonomic nervous system involvement that causes postural hypotension, arrhythmias, facial flushing, abnormalities of sweating, and urinary retention is common. Pain is another common feature of Guillain-Barré syndrome. Guillain-Barré syndrome may have a rapid development of ventilatory failure and autonomic disturbances that threaten circulatory function or it may present as a slow, insidious process.

Treatment. Treatment includes support of vital functions and prevention of complications such as skin breakdown and thrombophlebitis. Treatment is most effective if initiated early in the course of the disease.18 Plasmapheresis and high-dose intravenous immunoglobulin therapy are generally the mainstay of treatment.

Back Pain

Low back pain or low back strain is a common problem that affects almost 70% of people at least once in their lifetime.16,19 It affects men and women equally, with onset most often occurring between the ages of 30 and 50 years.18 Risk factors include heavy lifting, twisting, bodily vibration, obesity, and poor conditioning. However, low back pain is common even in people without these risk factors. Although acute low back pain resolves within 3 to 6 weeks in most people, recurrences are common.18

Back pain can result from a number of interrelated problems involving spinal structures, including facet joints, vertebral periosteum, ligaments, paravertebral musculature and fascia, and spinal nerve roots. People with low back pain frequently experience musculoligamentous injuries and age-related degenerative changes in the intervertebral disks and facet joints. Other causes include disk herniation, which is a herniated nucleus pulposus and spinal stenosis, which...
is characterized by narrowing of the central canal, typically from hypertrophic degenerative changes.\textsuperscript{16}

The diagnostic measures used in the evaluation of back pain include history and physical examination, including a thorough neurologic examination. Other diagnostic methods include radiographs of the back and magnetic resonance imaging (MRI). MRI or radiography is not generally recommended early in the course of low back pain. The diagnostic challenge is to identify those people who require further evaluation for more serious problems.

Treatment of back pain usually is conservative and consists of analgesic medications, muscle relaxants, and instruction in the correct mechanics for lifting and methods of protecting the back.\textsuperscript{16} Pain relief is usually provided using nonsteroidal anti-inflammatory drugs, other analgesics, and muscle relaxants. Due to the overwhelming frequency of sleep disorders with low back pain, it is important for the provider to also manage the sleep problem.\textsuperscript{20}

**Herniated Intervertebral Disk**

The intervertebral disk is considered the most critical component of the load-bearing structures of the spinal column. The intervertebral disk consists of a soft, gelatinous center called the \textit{nucleus pulposus}, which is encircled by a strong, ring-like collar of fibrocartilage called the \textit{annulus fibrosus}.\textsuperscript{2} The structural components of the disk make it capable of absorbing shock and changing shape while allowing movement. With dysfunction, the nucleus pulposus can be squeezed out of place and herniate through the annulus fibrosus, a condition referred to as a herniated, ruptured, or slipped disk (Fig. 19.9A and B).

**Etiology and Pathogenesis.** The intervertebral disk can become dysfunctional because of trauma, the effects of aging, or degenerative disorders of the spine. Trauma results from activities such as lifting while in the flexed position, slipping, falling on the buttocks or back, or suppressing a sneeze. With aging, the gelatinous center of the disk dries out and loses much of its elasticity, causing it to fray and tear. Degenerative processes such as osteoarthritis or ankylosing spondylitis predispose to malalignment of the vertebral column.

The cervical and lumbar regions are the most flexible areas of the spine and are most often involved in disk herniations. Usually, herniation occurs at the lower levels of the lumbar spine, where the mass being supported and the bending of the vertebral column are greatest. Most lumbar herniations occur in the L4 or L5 to S1 regions. With herniations of the cervical spine, the most frequently involved levels are C6 to C7 and C5 to C6. Protrusion of the nucleus pulposus usually occurs posteriorly and toward the intervertebral foramen and its contained spinal nerve root (see Fig. 19.9B).

The level at which a herniated disk occurs is important. When the injury occurs in the lumbar area, only the nerve fibers of the cauda equina are involved. Because these elongated dorsal and ventral roots contain endoneurial tubes of connective tissue, regeneration of the nerve fibers is likely. However, several weeks or months are required for full recovery to occur because of the distance to the innervated muscle or skin of the lower limbs.

**Clinical Manifestations.** The signs and symptoms of a herniated disk are localized to the area of the body innervated by the nerve roots and include both motor and sensory manifestations (Fig. 19.10). Pain is the first and most common symptom of a herniated disk. The nerve roots of L4, L5, S1, S2, and S3 give rise to a syndrome of back pain that spreads down the back of the leg and over the sole of the foot. The pain is usually intensified with coughing, sneezing, straining, stooping, standing, and the jarring motions that occur during walking or riding. Slight motor weakness may occur, although major weakness is rare. The most common sensory deficits from spinal nerve root compression are paresthesias and numbness, particularly of the leg and foot. A herniated disk must be differentiated from other causes of acute back pain.

suggests that using alternative treatments such as prolotherapy (PrT) impacts refractory low back pain by assisting to heal the soft tissue. Conditioning exercises of the trunk muscles, particularly the back extensors, are generally recommended. Surgical treatment may be indicated when there is documentation of herniation by an imaging procedure, consistent pain, or consistent neurologic deficit that has failed to respond to conservative therapy.

Back Pain Emergencies

Although acute back pain is usually a non–life-threatening condition, for a few people it can be a manifestation of serious pathology. Vascular catastrophes (abdominal and dissecting aortic aneurysms), malignancy, spinal cord compression syndromes, and infectious processes may all present as acute back pain.

Clinical findings, commonly referred to as red flags, which indicate the possibility of more serious disease include:

- Gradual onset of pain
- Age younger than 20 years or older than 50 years
- Thoracic back pain
- History of trauma, fever, chills, night sweats, immunosuppression, or malignancy
- Unintentional weight loss
- Recent procedure known to cause bacteremia
- History of intravenous drug use

The gradual onset of pain may be indicative of malignancy or infection. Back pain that begins before 20 years of age suggests congenital or developmental disorders, and new-onset pain in people 50 years of age or older is more likely to be a manifestation of serious conditions such as an aortic aneurysm, malignancy, or compression fracture. Pain that is aggravated by lying down is a red flag for malignancy or infection; and pain that improves with sitting or slight flexion of the spine suggests the presence of spinal stenosis. Reports of neurologic symptoms such as paresthesia, motor weakness, urinary or fecal incontinence, or gait abnormalities require additional diagnostic tests to rule out spinal cord compression.

Diagnosis. Diagnostic measures include history and physical examination. Neurologic assessment includes testing of muscle strength and reflexes. The straight-leg test is an important diagnostic maneuver. It is done in the supine position and is performed by passively raising the person’s leg. The test can also be done by slowly extending the knee while the person sits on a table, with both hip and knee flexed at 90 degrees. The maneuver is designed to apply traction along the nerve root, which exacerbates pain if the nerve root is acutely inflamed. Normally, it is possible to raise the leg approximately 90 degrees without causing discomfort of the hamstring muscles. The test result is positive if pain is produced when the leg is raised to 60 degrees or less. Other diagnostic methods include radiographs of the back, MRI, computed tomography (CT), and CT myelography.

Treatment. Treatment usually is conservative and consists of analgesic medications and education on how to protect the back. Pain relief usually can be provided using nonsteroidal anti-inflammatory drugs, although short-term use of opioid pain medications may be required for severe pain. Muscle relaxants may be used on a short-term basis. Evidence suggests that using alternative treatments such as prolotherapy (PrT) impacts refractory low back pain by assisting to heal the soft tissue. Conditioning exercises of the trunk muscles, particularly the back extensors, are generally recommended. Surgical treatment may be indicated when there is documentation of herniation by an imaging procedure, consistent pain, or consistent neurologic deficit that has failed to respond to conservative therapy.

IN SUMMARY

The motor unit consists of the LMN, the neuromuscular junction, and the skeletal muscle that the nerve innervates. Disorders of the neuromuscular unit include muscular dystrophy and myasthenia gravis. Muscular dystrophy is a term used to describe a number of disorders that produce progressive deterioration of skeletal muscle due to necrosis followed by fibrofatty tissue replacement. One form, DMD, is inherited as an X-linked trait and transmitted by the mother to her male offspring. Myasthenia gravis is a disorder of the neuromuscular junction resulting from a deficiency of functional acetylcholine receptors, which causes weakness of the skeletal muscles. Because the disease affects the neuromuscular junction, there is no
loss of sensory function. The most common manifestations are weakness of the eye muscles, with ptosis and diplopia. Peripheral nerve disorders involve motor and sensory neurons outside the CNS. There are two main types of peripheral nerve injury based on target of the insult: segmental demyelination involving the Schwann cell, and axonal degeneration involving the nerve axon or cell body. Peripheral nerve disorders include mononeuropathies, involving a single spinal nerve, plexus, or peripheral nerve, and polyneuropathies that involve demyelination or axonal degeneration of multiple peripheral nerves that leads to symmetric sensory, motor, or mixed sensorimotor deficits. Carpal tunnel syndrome, a mononeuropathy, is caused by compression of the median nerve that passes through the carpal tunnel in the wrist. Guillain-Barré syndrome is a subacute polyneuropathy, probably due to immune mechanisms, that causes progressive ascending motor, sensory, and autonomic nervous system manifestations. Respiratory involvement may occur and necessitate mechanical ventilation.

Acute back pain is most commonly the result of conditions such as muscle strain; treatment focuses on measures to improve activity tolerance. A herniated intervertebral disk is characterized by protrusion of the nucleus pulposus into the spinal canal with irritation or compression of the nerve root. Usually, herniation occurs at the lower levels of the lumbar and sacral (L4 or L5 to S1) and cervical (C6 to C7 and C5 to C6) regions of the spine. The signs and symptoms of a herniated disk are localized to the area of the body innervated by the affected nerve roots and include pain and both motor and sensory manifestations.

**DISORDERS OF THE CEREBELLM AND BASAL GANGLIA**

After completing this section of the chapter, you should be able to meet the following objectives:

- Relate the functions of the cerebellum to production of vestibulocerebellar ataxia, decomposition of movement, and cerebellar tremor.
- Describe the functional organization of the basal ganglia and communication pathways with the thalamus and cerebral cortex.

**Disorders of the Cerebellum**

The cerebellum is a structure located in the posterior fossa and attached to the pons, medulla, and midbrain by the three paired cerebellar peduncles. It has sometimes been referred to as the silent area of the brain because electrical stimulation does not produce any conscious sensation and rarely causes any motor movements. However, removal or damage to the cerebellum causes movements to become highly abnormal. The cerebellum is especially vital during rapid muscular activities such as running, typing, and even talking. Loss of cerebellar function can result in total incoordination of these functions even though paralysis does not ensue.

The functions of the cerebellum are integrated into many connected afferent and efferent pathways throughout the brain. An extensive and important afferent pathway is the corticopontocerebellar pathway, which originates in the cerebral motor and premotor cortices as well as the somatosensory cortex. Other important afferent pathways link the cerebellum to input from the basal ganglia, muscle and joint tension information from the stretch receptors, visual input from the eyes, and balance and equilibrium sensation from the vestibular system in the inner ear. There are three general efferent pathways leading out of the cerebellum:

- **Vestibulocerebellar pathway**: functions in close association with the brain stem vestibular nuclei to maintain equilibrium and posture
- **Spinocerebellar pathway**: provides the circuitry for coordinating the movements of the distal portions of the limbs, especially the hands and fingers
- **Cerebrocerebellar pathway**: transmits output information in the upward direction to the brain, functioning in a feedback manner with the motor and somatosensory systems to coordinate sequential body and limb movements

**Cerebellum-Associated Movement Disorders**

The signs of cerebellar dysfunction can be grouped into three classes—vestibulocerebellar disorders, cerebellar ataxia or decomposition of movement, and cerebellar tremor. These disorders occur on the side of cerebellar damage and are caused by congenital defect, vascular accident, or growing tumor. Visual monitoring of movement cannot compensate for cerebellar defects, and the movement abnormalities occur whether the eyes are open or closed.

Damage to the part of the cerebellum associated with the vestibular system leads to difficulty or inability to maintain a steady posture of the trunk, which normally requires constant readjusting movements. This is seen as an unsteadiness of the trunk, called truncal ataxia, and can be so severe that standing is not possible. The ability to fix the eyes on a target also can be affected. Constant conjugate readjustment of eye position, called nystagmus, results and makes reading extremely difficult, especially when the eyes are deviated toward the side of cerebellar damage.

Cerebellar ataxia and tremor are different aspects of defects in the smooth, continuously correcting functions. Cerebellar dystaxia or, if severe, ataxia is characterized by a decomposition of movement, with each succeeding component of a complex movement occurring separately instead of being blended into a smoothly proceeding action. Because ethanol specifically affects cerebellar function, people who are inebriated often walk with a staggering and unsteady gait. Rapid alternating movements such as supination–pronation–supination of the hands are jerky and performed slowly. Reaching to touch a target breaks down...
into small sequential components, each going too far, followed by overcorrection. The finger moves jerkily toward the target, misses, corrects in the other direction, and misses again, until the target is finally reached. This is called over- and underreaching or dysmetria. Multiple sclerosis (MS) is the most common cause of cerebellar ataxia. It is rare for children to have acute cerebellar ataxia, but the most common virus associated with this manifestation in children is varicella.

Cerebellar tremor is a rhythmic back-and-forth movement of a finger or toe that worsens as the target is approached. The tremor results from the inability of the damaged cerebellar system to maintain ongoing fixation of a body part and to make smooth, continuous corrections in the trajectory of the movement; overcorrection occurs, first in one direction and then the other. Often, the tremor of an arm or leg can be detected during the beginning of an intended movement. The common term for cerebellar tremor is intention tremor. It is possible to assess cerebellar function as it relates to tremor by asking a person to touch one heel to the opposite knee, to gently move the toes along the back of the opposite shin, or to touch the nose with a finger.

Cerebellar function also can affect the motor skills of chewing and swallowing (dysphagia) and of speech (dysarthria). Normal speech requires smooth control of respiratory muscles and highly coordinated control of the laryngeal, lip, and tongue muscles. Cerebellar dysarthria is characterized by slow, slurred speech of continuously varying loudness. Speech therapy can provide rehabilitative efforts, including learning to slow the rate of speech and to compensate as much as possible through the use of less-affected muscles.

**Disorders of the Basal Ganglia**

The basal ganglia are a group of deep, interrelated subcortical nuclei that provide an essential role in control of movement. They function in the organization of inherited and highly learned and rather automatic movement programs, especially those affecting the trunk and proximal limbs. The basal ganglia are thought to be particularly important in starting, stopping, and monitoring movements ordered and executed by the cortex, especially those that are relatively slow and sustained, or stereotyped, such as arm-swinging during walking. They also help to regulate the intensity of these movements, and they act to inhibit antagonistic or unnecessary movements. The function of the basal ganglia is not limited to motor functions. They also are involved in cognitive and perceptual functions.

The structural components of the basal ganglia include the caudate nucleus, putamen, and the globus pallidus. They are located lateral and caudal to the thalamus, occupying a large portion of the interior of both cerebral hemispheres. The caudate and putamen are collectively referred to as the *striatum*, and the putamen and the globus pallidus form a wedge-shaped region called the *lentiform nucleus*. Two other structures, the *substantia nigra* of the midbrain and *subthalamic nucleus* of the diencephalon, are considered part of the basal ganglia (Fig. 19.11). The dorsal part of the substantia nigra contains cells that use dopamine as a neurotransmitter and are rich in a black pigment called melanin. The high concentration of melanin gives the structure a black color, hence the name *substantia nigra*. The axons of the substantia nigra form the nigrostriatal pathway, which supplies dopamine to the striatum. The subthalamic nucleus lies just below the thalamus and above the anterior portion of the substantia nigra. The glutaminergic cells of this nucleus are the only excitatory projections to the basal ganglia.

Associated with the basal ganglia are several thalamic nuclei. For the motor and premotor cortices, these nuclei are the ventral lateral (VL) and the ventral anterior (VA) nuclei. Each region of the cerebral cortex is interconnected with a corresponding region of the ventral row of thalamic nuclei. The cortex-to-thalamus and thalamus-to-cortex feedback circuits are excitatory and, if unmodulated, would produce hyperactivity of the cortical area, causing stiffness and rigidity of the face, body, and limbs, and, if alternating, a continuous tremor (i.e., tremor at rest). For many semiautomatic stereotyped movements, thalamic excitability is modulated through inhibition by the basal ganglia. The basal ganglia form a major component of an inhibitory loop from each specific cortical region. Discrete inhibitory cortex-to-basal ganglia and thalamus-to-cortex loops modulate the function of all cerebral cortex regions.

The basal ganglia have input structures that receive afferent information from outside structures, internal circuits that connect the various structures of the basal ganglia, and output structures that deliver information to other brain centers. The striatum represents the major input structure for the basal ganglia. Virtually all principal pathways for executing learned
patterns of movement pass through the striatum. Other basal ganglia structures such as the substantia nigra and subthalamic nuclei are interconnected to one another or with the input and output nuclei and are considered to be components of the internal structures.

The output functions of the basal ganglia are mainly inhibitory. Looping circuits from specific cortical centers pass through the basal ganglia to modulate the excitability of certain thalamic nuclei and thus influence the cortical control of highly learned, automatic, and stereotyped motor functions. The two output nuclei of the basal ganglia, the globus pallidus and the substantia nigra, tonically inhibit their target nuclei in the thalamus. The basal ganglia also have a cognitive function. This function is closely connected with the cerebral cortex in that the basal ganglia monitor sensory information coming into the brain and apply it to information stored in memory. The cognitive control of motor activities determines, subconsciously and within seconds, which patterns of movement will be needed to achieve a goal. The caudate nucleus, which receives large amounts of input from the association areas of the brain, plays a major role in the cognitive control of motor activity.

Multiple pathways provide excitatory signals that balance the large number of inhibitory signals transmitted by GABA (γ-aminobutyric acid) ergic and dopaminergic neurons. One of these circuits involves a neostriatal inhibitory projection on the substantia nigra. The substantia nigra projects dopaminergic axons back on the striatum. Parkinsonism is a deficiency in the dopaminergic projection of this modulating circuit.

The function of the striatum also involves local cholinergic interneurons. The destruction of these interneurons is thought to be related to the choreiform movements of Huntington disease, another basal ganglia-related syndrome.

**Basal Ganglia– Associated Movement Disorders**

Disorders of the basal ganglia comprise a complex group of motor disturbances characterized by tremor and other involuntary movements, changes in posture and muscle tone, and poverty and slowness of movement. They include tremors and tics, hypokinetic disorders, and hyperkinetic disorders (Table 19.1).

Lesions of the basal ganglia disrupt movement. The various types of involuntary movements often occur in combination and appear to have a common underlying cause. There are hypokinetic and hyperkinetic disorders, which can be explained as having pathology in the indirect or direct pathways linking the basal ganglia with the thalamocortical motor circuit. Overactivity of the indirect pathway relative to the direct pathway would result in hypokinetic disorders such as Parkinson disease. Underactivity of the indirect pathway would result in hyperkinetic disorders such as chorea and ballismus.

**Parkinson Disease**

Parkinson disease is a degenerative disorder of basal ganglia function that results in variable combinations of tremor, rigidity, akinesia/bradykinesia, and postural changes. The disorder

is characterized by progressive destruction of the nigrostriatal pathway, with subsequent reduction in striatal concentrations of dopamine. The prevalence of Parkinson disease in the United States is estimated at 1.0% of the population over 65 years of age.16 The mean onset of Parkinson disease is 57 years of age, with approximately 60,000 new cases being diagnosed annually.

The clinical syndrome arising from the degenerative changes in basal ganglia function often is referred to as parkinsonism. In Parkinson disease, also known as idiopathic parkinsonism, dopamine depletion results from degeneration of the dopamine nigrostriatal system. Parkinsonism can also develop as a postencephalic syndrome, as a side effect of therapy with antipsychotic drugs that block dopamine receptors, as a toxic reaction to a chemical agent, or as an outcome of severe carbon monoxide poisoning. In addition, symptoms of parkinsonism can occur when damage to the nigrostriatal pathway occurs in such conditions as cerebral vascular disease, brain tumors, repeated head trauma, or a degenerative neurologic disease.

The primary brain abnormality found in all people with Parkinson disease is degeneration of the nigrostriatal dopamine neurons.16 On microscopic examination, there is loss of pigmented substantia nigra neurons (Fig. 19.12). Some residual nerve cells are atrophic, and few contain Lewy bodies, which are visualized as spherical, eosinophilic cytoplasmic inclusions. Lewy bodies are produced inside degenerated neurons in many people with Parkinson disease or parkinsonism.16

**Etiology and Pathogenesis.** Although the cause of Parkinson disease is still unknown, it is widely believed that most cases are caused by an interaction of environmental and genetic factors. Over the past several decades, several pathologic processes (e.g., oxidative stress, apoptosis, and mitochondrial disorders) that might lead to degeneration have been identified as causes of Parkinson disease. One study found that welders, who are continuously exposed to manganese, experienced manifestations of neurotoxicity similar to but different from people who have Parkinson disease.24 The evidence suggests that welders may have an occupational hazard of developing Parkinson disease more often compared to people not exposed to manganese.16 Certainly there are multiple other toxins in the environment that, similar to manganese, trigger neurotoxic problems, which may lead to parkinsonism. Multiple genes have been identified that illustrate there are different types of Parkinson disease depending on whether the person inherits a dominant or recessive gene.25 In fact, it has been found that the recessive form causes a milder set of symptoms than the dominant form, which resembles the more complex and severe form of Parkinson disease with Lewy bodies.25 Although rare, the autosomal dominant form of the disease has received considerable attention because α-synuclein is one of the major components of the Lewy bodies that are found in brain tissue of people with Parkinson disease.25 Mutations in a second gene coding the protein parkin is associated with an autosomal recessive, early-onset form of Parkinson disease. The parkin protein acts as an enzyme (i.e., ubiquitin ligase) in the ubiquitin-conjugating system that targets defective and abnormally folded proteins for destruction. Loss of normal parkin function is postulated to cause abnormal proteins to aggregate and cause neurodegenerative changes.7 The relationship of genetics to Parkinson disease is beginning to provide more information that helps explain the etiology of parkinsonism, similar to the epidemiologic studies, which have identified multiple environmental risks.
proteomic, transcriptomic, lipidomic, and metabolomic molecules and signaling pathways that determine the diagnosis of Parkinson disease.25 There are also syndromes that can cause parkinsonism and not the actual idiopathic Parkinson disease such as 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP)-induced parkinsonism, postinfarction parkinsonism, striatogniral degeneration, and progressive supranuclear palsy where the common finding is loss of pigmented dopaminergic neurons in the substantia nigra.7

Clinical Manifestations. The cardinal manifestations of Parkinson disease are tremor, rigidity, and bradykinesia or slowness of movement.10 Tremor is the most visible manifestation of the disorder. The tremor affects the distal segments of the limbs, mainly the hands and feet; head, neck, face, lips, and tongue; or jaw. It is characterized by rhythmic, alternating flexion and contraction movements (4 to 6 beats/minute) that resemble the motion of rolling a pill between the thumb and forefinger. The tremor usually is unilateral, occurs when the limb is supported and at rest, and disappears with movement and sleep. The tremor eventually progresses to involve both sides of the body.

Rigidity is defined as resistance to movement of both flexors and extensors throughout the full range of motion. It is most evident during passive joint movement and involves jerky, cogwheel-type or ratchet-like movements that require considerable energy to perform. Flexion contractions may develop as a result of the rigidity. As with tremor, rigidity usually begins unilaterally but progresses to involve both sides of the body.

Bradykinesia is characterized by slowness in initiating and performing movements and difficulty with sudden, unexpected stopping of voluntary movements. Unconscious associative movements occur in a series of disconnected steps rather than in a smooth, coordinated manner. This is the most disabling of the symptoms of Parkinson disease. People with the disease have difficulty initiating walking and difficulty turning. While walking, they may freeze in place and feel as if their feet are glued to the floor, especially when moving through a doorway or preparing to turn. When they walk, they lean forward to maintain their center of gravity and take small, shuffling steps without swinging their arms, and they have difficulty changing their stride. Manifestations of advanced-stage parkinsonism include falls, fluctuations in motor function, neuropysychiatric disorders, and sleep disorders. Loss of postural reflexes predisposes to falling, often backward. Emotional and voluntary facial movements become limited and slow as the disease progresses, and facial expression becomes stiff and masklike. There is loss of the blinking reflex and a failure to express emotion. The tongue, palate, and throat muscles become rigid. The person may drool because of difficulty in moving the saliva to the back of the mouth and swallowing it. The speech becomes slow and monotonous, without modulation, and poorly articulated.

Because the basal ganglia also influence the autonomic nervous system, people with Parkinson disease often have excessive and uncontrolled sweating, sebaceous gland secretion, and salivation. Autonomic symptoms, such as lacrimation, dysphagia, orthostatic hypotension, thermal regulation, constipation, impotence, and urinary incontinence, may be present, especially late in the disease.

Cognitive dysfunction may also be an important feature associated with Parkinson disease. The most severe form of dementia is seen in about 20% of people with Parkinson disease. Deficits in visuospatial discrimination, frontal lobe executive function, and memory retrieval (compared with formation of new memories, as seen in Alzheimer disease) are more typical of the cognitive dysfunction seen in people with Parkinson disease than in other forms of dementia. Deficits in executive functioning may be among the earliest signs of cognitive decline, as evidenced by difficulty in planning, starting, and carrying out tasks. Dementia, when it does occur, is usually a late manifestation of the disease, and the rate of decline is slow compared with Alzheimer disease.

Treatment. The approach to treatment of Parkinson disease must be highly individualized. It is significant to realize that there is no treatment that will totally prevent the disease progression. Treatment only manages the symptoms.16 Nonpharmacologic interventions offer group support, education, daily exercise, and adequate nutrition. Botulinum toxin injections may be used in the treatment of dystonias such as eyelid spasm and limb dystonias that frequently are associated with Parkinson disease. People with parkinsonism other than idiopathic Parkinson disease usually do not respond significantly to medications developed for Parkinson disease.

Pharmacologic treatment usually is determined by the severity of symptoms. Antiparkinson drugs act by increasing the functional ability of the underactive dopaminergic system or by reducing the excessive influence of excitatory cholinergic neurons. Drugs that improve the function of the dopaminergic system include those that increase dopamine levels (levodopa), stimulate dopamine receptors (dopamine receptor agonists), or retard the breakdown of dopamine (monoamine oxidase inhibitors). Because dopamine transmission is disrupted in Parkinson disease, there is a preponderance of cholinergic activity, which may be treated with anticholinergic drugs.26

Dopamine does not cross the blood–brain barrier. Administration of levodopa, a precursor of dopamine that does cross the blood–brain barrier, has yielded significant improvement in clinical symptoms of Parkinson disease and remains the most effective drug for treatment. The evidence of decreased dopamine levels in the striatum in Parkinson disease led to the administration of large doses of the synthetic compound levodopa, which is absorbed from the intestinal tract, crosses the blood–brain barrier, and is converted to dopamine by centrally acting dopa decarboxylase. When levodopa (a decarboxylase inhibitor) is given in combination with carbidopa, the peripheral metabolism of levodopa is reduced, plasma levels of levodopa are increased and its half-life is longer, more levodopa is available for entry into the brain, and a smaller dose is needed.26 A later adverse effect of levodopa treatment is the so-called on–off phenomenon, in which frequent, abrupt, and unpredictable fluctuations in motor performance occur during the day. These fluctuations
include “on” periods without dyskinesia, “on” periods with dyskinesia, and periods of bradykinesia (the “off” response). Some fluctuations reflect the timing of drug administration, in which case the “on” response coincides with peak drug levels and the “off” response with low drug levels.

Bromocriptine, pramipexole, and ropinirole are examples of dopamine agonists that directly stimulate dopamine receptors. Rotigotine is a dopamine agonist that is supplied in a transdermal system. Apomorphine is another dopamine agonist that can be given intravenously. Bromocriptine, pramipexole, and ropinirole can be used as initial or adjunctive therapy in Parkinson disease. They can be given in combination with carbidopa/levodopa. Selegiline and rasagiline are monoamine oxidase type B inhibitors that inhibit the metabolic breakdown of dopamine. Selegiline and rasagiline may be used as adjunctive treatment to reduce mild on–off fluctuations in the responsiveness of people who are receiving levodopa.

Anticholinergic drugs (e.g., trihexyphenidyl, benztprine) are thought to restore a “balance” between reduced dopamine and uninhibited cholinergic neurons in the striatum. They are more useful in alleviating tremor and rigidity than bradykinesia. The anticholinergic drugs lessen the tremors and rigidity and afford some improvement of function. However, their potency seems to decrease over time, and increasing the dosage merely increases side effects such as blurred vision, dry mouth, bowel and bladder problems, cognitive dysfunction, and hallucinations.

Before the advent of deep brain stimulation, surgical treatment for Parkinson disease was limited to thalamotomy and pallidotomy, which also caused destruction of brain tissue. With these procedures, part of the thalamus or globus pallidus in the basal ganglia is destroyed using an electrical stimulator or supercooled tip of a metal probe (cryothalamotomy). Brain mapping is done during the surgery to identify and prevent injury to sensory and motor tracts. Thalamotomy and pallidotomy are generally confined to one side of the brain because of adverse effects associated with bilateral lesioning procedures. Surgical transplantation of adrenal medullary tissue or fetal substantia nigra tissue was studied in clinical trials, but neither was proven to be helpful.

Deep brain stimulation, which involves the implantation of electrodes into the subthalamic nuclei or the pars interna of the globus pallidus, is performed more frequently for treatment of Parkinson disease in the United States since it is considered to be nondestructive and reversible. The electrodes are connected to a surgically implanted impulse generator that delivers electrical simulation to block the abnormal nerve activity that causes tremor and abnormal motor activity in Parkinson disease. The deep brain stimulation system allows the stimulation to be programmed to control the individual patient’s symptoms, and the stimulation parameters can be changed over time as the disease progresses. Deep brain stimulation is used for people with Parkinson disease who respond to levodopa but experience side effects associated with it (e.g., motor fluctuation or dyskinesia). It is not a cure but serves to increase the duration of the “on” periods, allows for a reduction in medication dosages (in subthalamic nuclei stimulation), and improves function.

**IN SUMMARY**

Alterations in coordination of muscle movements and abnormal muscle movements result from disorders of the cerebellum and basal ganglia. The functions of the cerebellum, which are especially vital during rapid muscular movements, use afferent input from various sources, including the stretch receptors, proprioceptors, tactile receptors in the skin, visual input, and vestibular system. Cerebellar disorders include vestibulocerebellar dysfunction, cerebellar ataxia, and cerebellar tremor.

The basal ganglia organize basic movement patterns into more complex patterns and release them when commanded by the motor cortex, contributing gracefulness to cortically initiated and controlled skilled movements. Disorders of the basal ganglia are characterized by involuntary movements, alterations in muscle tone, and disturbances in posture. These disorders include tremor, tics, hemiballismus, chorea, athetosis, dystonias, and dyskinesias.

Parkinsonism, a disorder of the basal ganglia, is characterized by destruction of the nigrostriatal pathway, with a subsequent reduction in striatal concentrations of dopamine. This results in an imbalance between the inhibitory effects of dopaminergic basal ganglia functions and an increase in the excitatory cholinergic functions. The disorder is manifested by resting tremor, increased muscle tonus and rigidity, slowness of movement (i.e., bradykinesia), gait disturbances, and impaired autonomic postural responses. The disease usually is slowly progressive over several decades. The tremor often begins in one or both hands and then becomes generalized. Postural changes and gait disturbances continue to become more pronounced, resulting in significant disability.

**UPPER MOTOR NEURON DISORDERS**

After completing this section of the chapter, you should be able to meet the following objectives:

- Relate the pathologic UMN and LMN changes that occur in amyotrophic lateral sclerosis (ALS) to the manifestations of the disease.
- Explain the significance of demyelination and plaque formation in MS.
- State the effects of SCI on ventilation and communication, the autonomic nervous system, cardiovascular function, sensorimotor function, and bowel, bladder, and sexual functions.
UMN disorders involve neurons that are fully contained within the CNS. They include the motor neurons arising in the motor areas of the cortex and their fibers as they project through the brain and descend in the spinal cord. ALS is a mixed UMN and LMN disorder. Disorders that affect UMN include MS and SCI.

Amyotrophic Lateral Sclerosis

Amyotrophic lateral sclerosis, also known as Lou Gehrig disease after the famous New York Yankees baseball player, is a devastating neurologic disorder that selectively affects motor function. ALS has an annual incidence of 1 per 100,000 population. ALS is primarily a disorder of middle to late adulthood, affecting people most frequently in their fifties, with men developing the disease nearly twice as often as women.

ALS affects motor neurons in three locations—the anterior horn cells (LMNs) of the spinal cord; the motor nuclei of the brain stem, particularly the hypoglossal nuclei; and the UMN of the cerebral cortex. The fact that the disease is more extensive in the distal parts of the affected tracts in the lower spinal cord rather than the proximal parts suggests that affected neurons first undergo degeneration at their distal terminals and that the disease proceeds until ultimately the parent nerve cell dies. A remarkable feature of the disease is that the entire sensory system, the regulatory mechanisms of control and coordination of movement, and the intellect remain intact. The neurons for ocular motility and the parasympathetic neurons in the sacral spinal cord also are spared.

The death of LMNs leads to denervation, with subsequent shrinkage of musculature and muscle fiber atrophy. It is this fiber atrophy, called amyotrophy, which appears in the name of the disease. The loss of nerve fibers in lateral columns of the white matter of the spinal cord, along with fibrillar gliosis, imparts a firmness or sclerosis to this CNS tissue. The term lateral sclerosis designates these changes.

Etiology and Pathogenesis

The cause of LMN and UMN destruction in ALS is uncertain. Five percent of cases are familial. The others are believed to be sporadic, with no family history of the disease. The gene for a subset of familial ALS has been mapped to superoxide dismutase 1 (SOD1) on chromosome 21. The neurofilament proteins, which function in the axonal transport of molecules, are destroyed with ALS. Other genetic loci for ALS have been mapped but not yet cloned. Another suggested mechanism of pathogenesis in ALS is exotoxic injury through activation of glutamate-gated ion channels, which are distinguished by their sensitivity to N-methyl-D-aspartic acid. Although autoimmune has been suggested as a cause of ALS, the disease does not respond to the immunosuppressant agents that normally are used in treatment of autoimmune disorders.

Clinical Manifestations

The symptoms of ALS may be referable to UMN or LMN involvement. Manifestations of UMN lesions include weakness, spasticity or stiffness, and impaired fine motor control. Dysphagia (difficulty swallowing), dysarthria (impaired articulation of speech), and dysphonia (difficulty making the sounds of speech) may result from brain stem LMN involvement or from dysfunction of UMN descending to the brain stem. Manifestations of LMN destruction include fasciculations, weakness, muscle atrophy, and hyporeflexia. Muscle cramps involving the distal legs often are an early symptom. The most common clinical presentation is slowly progressive weakness and atrophy in distal muscles of one upper extremity. This is followed by regional spread of clinical weakness, reflecting involvement of neighboring areas of the spinal cord. Eventually, UMNs and LMNs involving multiple limbs and the head are affected. In the more advanced stages, muscles of the palate, pharynx, tongue, neck, and shoulders become involved, causing impairment of chewing, swallowing, and speech. Dysphagia with recurrent aspiration and weakness of the respiratory muscles produces the most significant acute complications of the disease. Death usually results from involvement of cranial nerves and respiratory musculature.

Treatment

Currently, there is no cure for ALS. Management of people with ALS is challenging and requires a multidisciplinary team. Measures to assist people with the disorder to manage their symptoms (e.g., weakness and muscle spasms, dysphagia, communication difficulty, excessive watery saliva, and emotional lability), nutritional status, and respiratory muscle weakness allow people with the disorder to survive longer than would otherwise have been the case. An antiglutamate drug, riluzole, is the only drug approved by the FDA and Health Canada for treatment of ALS at this time. The drug is designed to decrease glutamate accumulation and slow the progression of the disease. Other neuroprotective treatments such as vaccine therapy, stem cell injections, and pacing of the diaphragm are in trial stages but, again, are not focused on stopping or eradicating the disease.

Multiple Sclerosis

As with other demyelinating disorders, MS is characterized by inflammation and destruction of mostly the white matter of the CNS myelin. The peripheral nervous system is spared, and there is usually no evidence of an associated systemic disease. MS is estimated to affect approximately 2.1 million people worldwide and 500,000 people in the United States. The age of onset is typically between 20 and 30 years, with women being affected twice as frequently as men. MS results in significant functional and often work-related disability in persons who are in the prime of their productivity.
Remember Ms. Ulrie, who you were introduced to in the Unit V case study opening scenario? Ms. Ulrie is a 22-year-old college student who was diagnosed with remitting–relapsing MS. Ms. Ulrie fits the age of onset of MS, which is typically between 20 and 30 years of age. She also has a family member with MS (her grandmother), and her female gender puts her at higher risk for MS compared to males. It will be challenging for Ms. Ulrie to be successful with her college studies during exacerbations of MS.

Etiology

MS occurs more commonly in people of European ancestry and is uncommon in certain ethnic groups such as Native Americans and Africans.29 The prevalence is low in Japan, in other parts of Asia, in equatorial Africa, and in the Middle East. It has been observed that the disease is more common in northern latitudes, perhaps related to the selective migration of people with a susceptible genetic background to these regions.29

The risk for developing MS is 1/40 when the disease is present in a first-degree relative.29 The risk without having any family history is 1/1000.7 People with the human leukocyte antigen HLA-DR2 haplotype are particularly susceptible.30 The molecular basis for the influence of this particular haplotype is being studied.30

Pathogenesis

MS is believed to be an immune-mediated disorder that occurs in genetically susceptible people. Although the target antigen has not been identified, the data suggest an immune response to a protein in the CNS.

The lesions of MS consist of hard, sharp-edged, demyelinated patches that are visible throughout the white matter as well as sometimes the gray matter of the CNS7 (Fig. 19.13).

These lesions, which represent the end result of acute myelin breakdown, are called plaques. The lesions have a predilection for the optic nerves, periventricular white matter, brain stem, cerebellum, and spinal cord white matter.7 In an active plaque, there is evidence of ongoing myelin breakdown. The sequence of myelin breakdown is not well understood, although it is known that the lesions contain small amounts of myelin basic proteins and increased amounts of proteolytic enzymes, macrophages, lymphocytes, and plasma cells.

Clinical Manifestations and Course

The pathophysiology of MS involves the demyelination of nerve fibers in the white matter of the brain, spinal cord, and optic nerve. In the CNS, myelin is formed by the oligodendrocytes, chiefly those lying among the nerve fibers in the white matter. This function of the oligodendrocytes is equivalent to that of the Schwann cells in the peripheral nervous system. The properties of the myelin sheath—high electrical resistance and low capacitance—permit it to function as an electrical insulator. Demyelinated nerve fibers display a variety of conduction abnormalities, ranging from decreased conduction velocity to conduction blocks. The interruption of neural conduction in the demyelinated nerves is manifested by a variety of symptoms, depending on the location and extent of the lesion. Areas commonly affected by MS are the optic nerve (visual field), corticobulbar tracts (speech and swallowing), corticospinal tracts (muscle strength), cerebellar tracts (gait and coordination), spinocerebellar tracts (balance), medial longitudinal fasciculus (conjugate gaze function of the extraocular eye muscles), and posterior cell columns of the spinal cord (position and vibratory sensation). Typically,
